Abstract. The development of industrial technology also brings with optimized surface quality, particularly where there is contact with food. Application ultra-hydrophobic surface significantly reduces the growth of bacteria and facilitates cleaning processes. Testing and evaluation of surface quality are used two methods: impinging droplet and inclined surface method optimized with high speed shadowgraphy, which give information about dynamic contact angle. This article presents the results of research into new methods of measuring ultra-hydrophobic patented technology.

1 Introduction

So far the investigation of hydrophobic surfaces in fluid mechanics was solved on the macroscopic level. The problem of hydrophobic surfaces is very complex and can be crucial to fluid mechanics, especially the problem of adhesion of liquid on a solid surface that is set as boundary condition in the most of mathematical models.

The interdisciplinary project GA13-20031S deals with the research of hydrophobic surfaces. Based on feedback, teams cooperate and produce the coatings on the principle of using nano-plasma technology [1]. The aim is to gain basic knowledge about the movement of fluid in the contact layer between the liquid and the hydrophobic surface [2]. This knowledge is used to reduce hydraulic losses and the change in concentration of gases in liquids. Surface binding properties are studied in terms of surface energy, the adhesion coefficient. To the experimental study and analysed data are set in the mathematical model with new boundary conditions, using the adhesive coefficient, determining adhesion strength in the surface layer of hydrophobic surface to prove and validate the physical expressions [3]. This creates the prerequisites for the establishment of wall functions necessary for the formulation of the updated model of turbulence. Due to the traction fluid on the wall with hydrophobic properties, it changes the boundary layer and its stability. In addition, there will be changes in pressure, which forces the study of problems of cavitation. From the measurements it is possible to estimate the value of the contact angle of approximately 160° this corresponds with characteristics of super hydrophobic surface.

In 1823, set the Navier the basic relation for the liquids. Approximately 200 years ago, Thomas Young suggested a relationship for the contact angle of the liquid [4]. In 1937, Bangham, D. H., Razouk, R.I. pointed out the importance of negligence gas adsorption on the surface of the solid phase during the derivation of Young's equation [5]. In the following years have been done a lot of research on the measurement of fluid slip; both from the theoretical, and experimental point of view. However, the results were not very successful because there were not known the surfaces with sufficient degree of hydrophobic [6].

The measurements were performed with a small contact angle, so the fluid slip was negligible and measurable with a big mistake. Also, experimental methods were not sufficiently accurate [7]. These measurements clearly showed "nonslip" boundary condition. Additional experiments revealed that if the interactions between the liquid and the solid surface will be weaker, there is an increase of the slip; the hydrophobic surfaces have a length slip beneficial effect [8].

During the experimental examining of the surface roughness influence on the slip length, the authors diverge in their conclusions. Some experiments have shown that the surface roughness decreases the length of the slide; other experiments showed the opposite results. This phenomenon can be explained such that at full wetting of rough surface leads to reduction of the slip, while the partial wetting of the surface roughness creates favourable conditions for the formation of gas or vapour, resulting the increase of the slip length [9].

The hydrophobic surfaces are characterized with following properties: hydrodynamic drag that is an important issue in many fluid systems. The examination...
of this property can be used goniometer system [10]. The
typical property of the surface is the contact angle.

The contact angle measurements involve the sessile
drop or pendant drop technique that is widely used for
investigation of the surface characteristics of various
materials. Measuring this property we can also determine
the degree of water repellence [11]. Another point of view
on the evaluation of the hydrophobic surfaces offers the
experiments based on the online study of drop impact.

This kind of studies involving the drop impinging and
the movement of the defined droplet on the inclined
surface. Impacts of individual water droplets on
hydrophobic surfaces at slow velocities allow
identification of three distinct regimes of droplet
behaviour: rebound, pinning and fragmentation. This set
of inner conditions enable us state the kinetic energy that
is converted to deformational potential energy, due the
surface tension for liquids and elasticity for solids, and
appears as the translation motion and the internal drop
motion (waves, oscillations and dissipation).

2 Sample preparations

In this work are published results taken on the surfaces
produced by the plasma deposition technologies. The
plasma deposition can be provided by many various sub-
technologies, such as CVD, PVD, PECVD, spraying,
spinning, etc. Each named technology includes a wide
range of specific technologies, which differ from each
other as technological equipment and working conditions,
as well as the achieved results, i.e. the types and
composition of the various deposits and their properties,
structure, and chemical composition. Only some of them
exhibit nanostructured character.

The one way of making nanostructured thin films
especially with varying degrees of hydrophobicity of the
above plasma jet systems. These nanostructures are
suitable to modify any surface and make its basic value.
Another interesting form of nanostructures particularly in
terms of supporting or reinforcing permeable structures
are nanowire, which today can be prepared on an
industrial scale for many materials. Another example of
well-known application techniques nanostructured layers
are methods of creating a very fine aerosol that is applied
to the surface of the material. Practically, only two
aerosol generation technologies of hitherto commonly
used technologies allow you to generate sufficiently fine
and homogeneous aerosol with a narrow size distribution
of aerosol particles, which is suitable for creating defined
nanostructures, nanostructured layers or nano composite
materials.

The first generation of appropriate technology is
called aerosol electrostatic spraying in which either uses
electrospray nozzle or aerosol generated from a “free”
level using a modified electro spinning technology [12].

Using the plasma jet at atmospheric pressure for a
modification of macromolecular materials and surfaces is
disclosed in EP 07466017.6-1226 (Klima, M. et al.
2007). This application provides a method including
coating plasma structured macromolecular substances on
substrates of macromolecular substances. The plasma jet
or multi-jet system that generates plasma at atmospheric
pressure is based on principle of the hollow cathode
running with high frequency (13.56 MHz) - see Patent

The basis of jets currently uses dielectric capillaries of
silica or alumina, which working gas argon that flows
through the electrode. Dielectric capillary locked around
anode electrode or multi-electrode system. The
discharge is ignited pre ionized of environment in
dielectric capillary nozzle. The resulting plasma springs
from the cavity and the mouth of the plasma jet to the
external environment in which it operates on the surface.
Grouping of jets in the linear profile or matrix allows
working on larger areas. In the present study the new
linear types of plasma jets allowing greater homogeneity
of surface treatment and easier combination for aerosol
type precursors.

In this paper are published results measured with
following samples. Sample No.1 - ultra hydrophobic
layer obtained by direct deposition of HMDSO precursor
of argon plasma generated by plasma jets (multi jet-row
system 20 dielectric capillaries on the width 10 cm). Sample
No.2 and 3 were prepared by the same procedure,
i.e., first by the plasma, and the precursor was formed
HMDSO ultra hydrophobic layers, subsequently it was
applied to two different types according nanopolymer
sample (to improve stability and mechanical properties).
For sample No.2 was used nanopolymer based on SiO2 in
ethanol solution (classical Nano-glass) for the sample No.
3 was chosen based nanopolymer Fluor hydrocarbons in
aqueous solution (rubbed into the structure ultra-
hydrophobic layer). Samples No.4 and 5 were prepared
by the same procedure, i.e., first by the plasma, and the
precursor was formed HMDSO ultra hydrophobic layers
will, subsequently it was applied to two different types
according nanopolymer sample (to improve stability and
mechanical properties), the sample consists was also
briefly a modified plasma precursors HMDSO. For
sample No. 4 was used nanopolymer based on SiO2 in
ethanol solution (classical Nano-glass) for the sample No.
5 was chosen nanopolymer based Fluor hydrocarbons in
aqueous solution (rubbed into the structure ultra-
hydrophobic layer). Sample No.6 was formed by first
using plasma and precursor HMDSO was created ultra-
hydrophobic layers will, subsequently it was applied to a
thin layer of plasma precursor trimethyl boric acid (for
reinforcement structure).

3 Experimental setup

For the investigation of the manufactured samples we
used the optical method. The basic set up of the
shadowgraph method was completed and upgraded with
high speed camera SpeedSense – DantecDynamics and
software PCC2.1.

The data obtained from the measurement were
mathematically processed and analysed. The continuous
light source of 1.5 kWatt was focused to the path of the
drop and placed oppositely to the camera. Using this
setup with very small exposure time and the aperture
number 4 we obtain quality image with high contrast.
Images were received and digitized by a CCD high speed camera. The whole system, including storage of images, was controlled by a personal computer. The sample rate was set 5000 fps; the exposure time of the CCD-camera was 1.02 μs with image resolution (1280 × 800) pixels. During the measurement we used the pre trigger of 1 sec time and the measurement was synchronized by the photocell.

For the examination of the sample we used the impinging droplet method and the method of inclined surface.

The impinging drop method give us information about wettability of the substrate that can be also described with the contact angle and the second condition that can influence the droplet behaviour is the surface average roughness. Using this method we can study the process of droplet kinetic energy dissipation by viscous effects and surface energy that is demonstrated by dynamic behaviour.

The inclined wall method utilizes the conversion of translational kinetic energy into deformational potential energy. Here we used setup with the sample inclined under 20°. In both experimental setups the droplet was generated with the blunt needle nozzle of diameter 0.3 mm. For the inclined surface method the needle tip was placed 4mm above the surface to avoid the impinging and oscillating factor of the droplet movement. In the impinging droplet method, the needle tip was fit 15 mm above the surface.

In both cases as the medium liquid was used distilled water.

4 Results and discussion

Each sample mentioned above was tested with the impinging droplet method as well as with water drop motion on the inclined surface.

Using the inclined surface method we achieved the information about the basic characters of the droplet movement on the investigated surface. Even from this basic primitive observation we recognized the main difference between the samples. This measurement also uncovered instabilities and no uniformities of the provided samples. During the measurement we followed the path of the single one droplet and afterwards the sample was moved to the original path with micrometric traverser. This setup enabled scanning the whole sample condition so we got the complex information about the sample. The resulting chart of velocities is a statistic of the 15 measurements, where each measurement represents one droplet path.

Figure 1. The example of the shadowgraphy measurement of the droplet motion on the inclined surface – sample No. a) 3, b) 4 and c) 6

Using the inclined surface method we achieved the information about the basic characters of the droplet movement on the investigated surface. Even from this basic primitive observation we recognized the main difference between the samples. This measurement also uncovered instabilities and no uniformities of the provided samples. During the measurement we followed the path of the single one droplet and afterwards the sample was moved to the original path with micrometric traverser. This setup enabled scanning the whole sample condition so we got the complex information about the sample. The resulting chart of velocities is a statistic of the 15 measurements, where each measurement represents one droplet path.

The second part of sample testing involved the impinging droplet method. The images obtained by high speed camera with sampling rate 5000 were analysed in image processing software and we calculated both contact angle between the liquid and solid phase. The charts of result containing the time part, when the droplet is in the contact with substrate. The default point of measurement was set the first contact of droplet with surface with 1 px accuracy. The contact angle processing was finished, when the droplet left the surface. As the reference sample was determined the pure glass.
From the computing chart is well seen the respond of contact angle on the oscillation of the droplet, where predominates the elastic part of the kinetic energy.

Expected characteristic behaviour of the impinging droplet can be categorized in two types: corona splashing and prompt splashing. The observed behaviour of the water droplets has no significant features that can be easily classify into this two categories. The behaviour of the droplet remains mostly the liquid with higher viscosity. The splashing factor may be observed in different set up, means with the needle tip placed higher than 15 mm above the substrate. Analysing the captured images we were interested in the time track 0.06 sec, because here predominates the impact of the surface on the droplet behaviour. This impact also reflects the contact angle of the liquid.

The second important time track is the 0.12 sec, when the droplet leaves the substrate with characteristic profile and jumps in the certain height. This height of the first jump can be further analysed, because it seems to be another important characteristic of the super hydrophobic surface. This behaviour follows the wall friction law and slips effects and should be involved in the future studies as well as the physical analyses of the process.

The measurements of contact angles are shown in the graphs below. The selected results refer the different behaviour of the liquid phase. The first chart named “Pure Glass” follows the characteristic development of the sessile drop on the solid substrate with corresponding contact angles and interfacial behaviour that stabilise after 60 microseconds on 58°.

The samples No. 3, 5 and 6 show the same characteristics in the meaning that the contact angle profile is stable and varying about certain value that is significant for the sample. These samples demonstrate the typical statement of super hydrophobicity with the contact angles of value round 160°, and the low edge of hydrophobic value of contact angle was set to be 130°.

The sample No. 2 shows the characteristic of the hydrophobic surface, but without the antipearl effect that is very important in industrial applications. The droplet stays close the surface with great contact area.

Another interesting behaviour we can observe with sample No. 4. This behaviour lies between the sample No. 2 and antipearl effect. The liquid phase reacts on the contact with solid substrate with developing thin stem. This stem is finally cut, but stays significantly present on the profile of the impinged droplet.

5 Conclusions

This article brought information about novel patented method of super hydrophobic surface production. This method is suitable for industrial application requiring self-cleaning process.

We have described two methods that are useful for studies and visualization basic properties of these surfaces. They are both based on the optical measurement and further image processing.

The initial analyses uncovered the weakness of both method but also pointed the useful information that can be used in mathematical simulation for statement of boundary condition.
