The Muon g-2 experiment at Fermilab

Antoine Chapelain[1,a] On behalf of the Muon g-2 Collaboration

[1]*Cornell University, Department of Physics, 511 Clark Hall, Ithaca, NY 14853, USA*

Abstract. The upcoming Fermilab E989 experiment will measure the muon anomalous magnetic moment a_μ. This measurement is motivated by the previous measurement performed in 2001 by the BNL E821 experiment that reported a 3-4 standard deviation discrepancy between the measured value and the Standard Model prediction. The new measurement at Fermilab aims to improve the precision by a factor of four reducing the total uncertainty from 540 parts per billion (BNL E821) to 140 parts per billion (Fermilab E989). This paper gives the status of the experiment.

1 Introduction

The measurement of the anomalous part $a_{\ell=e,\mu}$ of the magnetic moment of the electron and muon is a high-precision test of the Standard Model (SM) of particle physics, and thus a good window to look for physics that lies beyond the SM (BSM). The sensitivity to BSM physics scales with $(m_\ell/\Lambda)^2$, Λ being the BSM physic energy scale,. The current best measurement of a_e [1] to 0.28 parts per trillion is 1929 more precise than the current best measurement of a_μ [2] to 0.54 parts per million (ppm). The muon to electron mass ratio of $(m_\mu/m_e) = 200$ results an expected BSM sensitivity ratio $(m_\mu/m_e)^2 = 40000$. In consequence, the muon sector is a more sensitive probe to look for BSM physic.

The measurement of a_μ reported in [2] by the BNL E821 experiment shows a 3.6 standard deviation difference from the SM prediction, which could be a sign for BSM physics such as super-symmetry [3, 4] or dark photon [5]. This tantalizing difference motivated the new experiment E989 at Fermilab by the Muon g-2 collaboration [6], which aims for a factor of four improvement in the total experimental uncertainty. E821 total systematic uncertainty was dominated by the statistical uncertainty. E989 aims to have the same contribution to the total uncertainty from systematics and statistics. It requires a much larger improvement for the statistical uncertainty with 21 times the E821 statistics. The total uncertainty improvement is discussed in Sections 4, 5 and 6. Section 2 below gives an overview of the theory status and Section 3 presents the measurement principle.

2 Theory

A charged fermion with electric charge $Q = \pm 1$ under the influence of a magnetic field B has a magnetic dipole moment

$$\vec{\mu} = g\frac{Q}{2m}\vec{s},\tag{1}$$

Table 1. Summary of the Standard-Model contributions to the muon anomalous magnetic moment [10].

	VALUE ($\times 10^{-11}$) UNITS
QED	116 584 718.95 ± 0.08
HVP	6 850.6 ± 43
HLbL	105 ± 26
EW	153.6 ± 1.0
Total SM	116 591 828 ± 49

where $\vec{s}$ is the spin of the particle and g the gyromagnetic ratio. We define the anomalous magnetic moment via the deviation of the gyromagnetic ratio from Eq. (1): $g = 2(1 + a_\mu)$. In the Dirac theory, which corresponds to leading order in QED , $g = 2$, and $a_\mu = 0$. Higher order contributions lead to $a_\mu \neq 0$. The current theoretical status for a_μ is presented in Table 1 [6]. The main contribution comes by far from QED, which is known to five loops (tenth order) and has a small, well-understood uncertainty. Sensitivity at the level of the electroweak (EW) contribution was reached by the E821 experiment. The hadronic contribution dominates the uncertainty (0.43 ppm compared to 0.01 ppm for QED and EW grouped together). This contribution splits into two categories, hadronic vacuum polarization (HVP) and hadronic light-by-light (HLbL). The HVP contribution dominates the correction, and can be calculated from $e^+e^- \rightarrow$ hadrons cross-section using dispersion relations. The HLbL contribution derives from model-dependent calculations. Lattice QCD predictions of these two hadronic contributions are becoming competitive, and will be crucial in providing robust uncertainty estimates free from uncontrolled modeling assumptions. Lattice QCD predictions have well-understood, quantifiable uncertainty estimates. Model-based estimates lack controlled uncertainty estimates, and will always allow a loophole in comparisons with the SM.

The uncertainties in the theory calculation are expected to improve by a factor of two on the timescale of the E989 experiment. This improvement will be achieved taking advantage of new data to improve both the HVP (BESIII [7], VEPP2000 [8] and B-factories data) and HLBL (KLOE-2 [9] and BESIII data), the latter gaining from the modeling improvements made possible with the new data. On the lattice QCD side, new ways of computing a_μ from first principles and an increase in computing capability will provide the expected gains. Given the anticipated improvements in both experimental and theoretical precision, if the central values remain the same there is a potential 7 standard deviation between theory and measurement (5 standard deviation with only experimental improvement). The situation is summarized in Fig. 1(a) [10].

3 Measurement principle

The E989 experiment at Fermilab follows the same measurement principle that was used by the previous E821 experiment. E989 reuses E821 the magnet which is a critical part of the experiment that produces the storage magnetic field to the require very high uniformity. A beam of positive muons with 96% polarization is produced from a beam of pions. The muons are injected into a weak focusing storage going through an inflector that cancels the dipole magnetic field of the storage ring. The trajectory of the muons at the exit of the inflector does not match the closed orbit of the ring. Three identical kickers will kick the beam onto the closed orbit providing a kick of about 11 mrad corresponding to a magnetic field of about 230 Gauss. The storage magnet only provides the radial focusing. Four electrostatic quadrupoles operating at 32 kV will provide the vertical focusing.
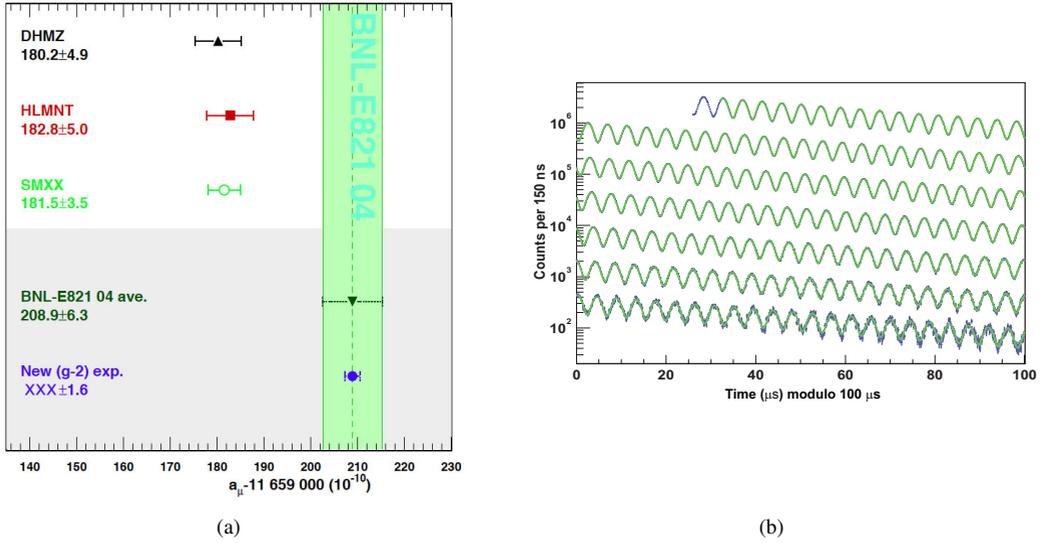

Figure 1. 1(a) Summary of the current SM prediction along with the BNL E821 measurement and the projected uncertainty on the incoming Fermilab E989 experiment. 1(b) Number of high-energy positrons versus time for the 2001 data set from the BNL E821 experiment.

Due to the magnetic field, the muon spin precesses relative to its momentum while the muon undergo a cyclotron motion with a frequency of 149 ns. Our measurement technique directly yields the anomalous spin precession frequency, the difference between the spin precession frequency and the cyclotron frequency, and depends directly on a_μ and the magnetic field strength B via

$$\vec{\omega_a} = \vec{\omega_S} - \vec{\omega_C} = \vec{\omega}_a = -\frac{Q}{m}\left[a_\mu\vec{B} - \left(a_\mu - \frac{1}{\gamma^2 - 1}\right)\frac{\vec{\beta} \times \vec{E}}{c}\right] \qquad (2)$$

The magnetic field arising from the boost of any laboratory electric fields to the muon rest frame contributes to the second term proportional to $\vec{\beta} \times \vec{E}$ in brackets of Eq. (2). In E989, the focusing quadrupole fields would make such a contribution. Fortunately, this contribution vanishes at first order for muons having the so-called "magic momentum" of 3.094 GeV/c ($\gamma = 29.3$), the momentum of the E821 and E989 stored beams.

The muon spin precession frequency is extracted using the positron from the muon decay as a proxy. Due to V-A nature of the muon decay, the highest energy positrons are emitted with their momentum parallel to the muon spin. When this dependence is couple to the boost from the muon rest frame to the lab frame, the rate of highest energy positrons in the lab frame experiences a modulation at the anomalous precession frequency ω_a. The ω_a frequency can thus be extracted by counting the number of positrons above an energy threshold (optimized for the best sensitivity) as a function of time. Figure 1(b) shows the modulated counting rate observed in the 2001 E821 data. The anomalous magnetic moment is determined measuring both ω_a and B via the relation

$$a_\mu = \frac{\omega_a}{\omega_p}\frac{\mu_p}{\mu_e}\frac{m_\mu}{m_e}\frac{g_e}{2}, \qquad (3)$$

Figure 2. Schematic of the Fermilab accelerator chain: from the proton to the muon beam.

where the proton-to-electron magnetic moment ratio μ_p/μ_e, the muon-to-electron mass ratio m_μ/m_e and the electron gyromagnetic ratio g_e come from other measurements as well as SM theory [11, 12].

The projected four-fold improvement on a_μ requires reducing the statistical uncertainty (limiting uncertainty for E821) by a factor four and the systematic uncertainty by a factor three. The following sections focus on these improvements.

4 First challenge: statistical uncertainty

The goal for the statistical uncertainty requires 21 times the E821 statistics, which is about 2×10^{11} detected positrons. This goal represents a great challenge given the Fermilab proton beam is 4 times less intense than the BNL proton beam. In consequence, a factor 84 improvement is required for the integrated luminosity. To achieve this goal, the muon injection efficiency into the storage will be higher for E989 compared to E821. There will be in consequence more muons stored into the ring. Also, the repetition rate is being increased from 0.37 Hz to 12 Hz on average.

Most of the Fermilab accelerator chain will be used to produce the muon beam (see Fig. 2). About 4×10^{12} 8 GeV protons from the Booster synchrotron will be injected into the Recycler ring at a 15 Hz rate. The protons will be re-organized in four bunches with 10 ms time separation and then sent to the pion production target. Pions with a 3.11 GeV/c momentum will be collected after the target using a Lithium lens and a dipole magnet. The pions are then sent to the Delivery ring. The Delivery ring allows spatial separation between the pions (most of them having decayed into muons) and the remaining protons to get rid off the protons. After the Delivery ring, the muon beam goes to the g-2 storage ring for a typical fill length of 700 μs. The typical muon injection efficiency is 2.4×10^{-7} per proton on target [13].

The accelerator chain described above has a longer $\pi \rightarrow \mu$ decay channel than the one at BNL. E989 will not suffer from a "pion flash" at the early time of the fill that E821 had to deal with. It results in a higher muon beam purity allowing the use of data at an earlier time.

Table 2. List of the major ω_a systematic uncertainties.

Category	E821 [ppb]	E989 Improvement Plans	Goal [ppb]
Intra-fill gain change	120	Better laser calibration	
		Low-energy threshold	20
Pileup	80	Low-energy samples recorded	
		Calorimeter segmentation	40
Lost muons	90	Better collimation in ring	20
CBO	70	Change CBO frequency	< 30
E and pitch	50	Improved tracker	
		Precise storage ring simulations	30
Total	180	Quadrature sum	70

5 Second challenge: ω_a systematic uncertainty

The main sources of systematic uncertainty $\delta\omega_a$ on ω_a are listed in Table 5 along with their values for E821 and the design goal for E989. New detector systems were designed in order to reduce the total systematic uncertainty on ω_a by a factor about 3.

Twenty four calorimeter stations will be deployed inside the ring to measure the energy and arrival time of the positrons. The segmented calorimeters (E821's calorimeter was not segmented) are made of an array of 6×9 lead-fluoride crystals and provide a fast response due to Čerenkov light. Each crystal is readout by a a 4x4 array of silicon photomultiplier (SiPM), whose signals are summed. The resulting waveform for the crystal is digitized at 800 MAP with 12-bit resolution (E821 had 200 MSPS 8-bit resolution digitizers). The digitizers are implemented as 5-channel AMC cards that operate in an industry standard μTCA crate. Etc.

The anticipated main contribution (40 ppb) to $\delta\omega_a$ comes from pile-up events when two positrons hit the same calorimeter nano-seconds or less apart. The calorimeter segmentation allows spatial separation of pile-up events. The digitization rate allows for time separation of pile-up events at nano-seconds time scale. The energy scale (gain) of the calorimeter will be measured using a laser calibration system. It is important to know accurately the intra-fill gain stability since the measurement of ω_a relies on counting the number of positrons above an energy threshold on a fill basis. The main design goals for the calorimeter system are:

1. Positron hit time measurement with an accuracy of 100 psec for a positron energy > 100 MeV;

2. The measured deposited energy must have a resolution better than 5% at 2 GeV;

3. Allow 100% pile-up separation above 5 nsec, and 66 % below 5 nsec;

4. Gain stability monitored at subpermill level over the course of 700 μs fill where rate varies by 10^4.

An end-to-end test of one complete calorimeter station was performed in June 2016 with the electron beam at the End Test Station B at the Stanford Linear Accelerator laboratory (SLAC). The electron beam had a primary energy of 3 GeV (ranged from 2.5 GeV to 5 GeV). The number of electron per beam pulse was chosen to be either one, two, three... according to the needs for pile-up studies. This test beam showed than the design requirements are fulfilled as illustrated in Fig. 3(a)-3(c). The electron hit time resolution (Fig. 3(a)) was determined using laser pulses that illuminated
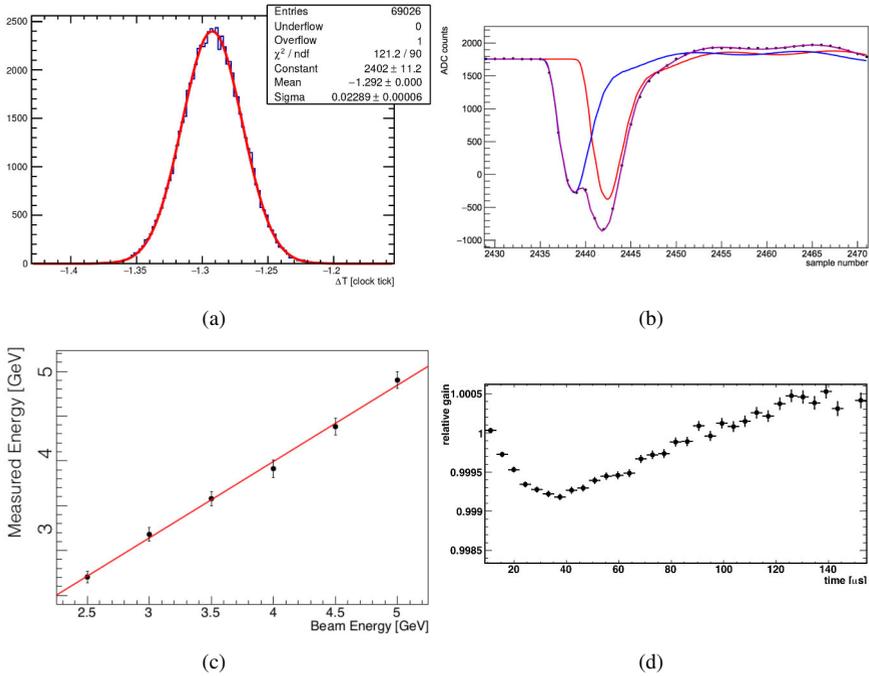

Figure 3. 3(a) Laser light hit time difference between two calorimeter crystal in unit of clock tick. The width of the distribution is the time resolution considering two crystals at the same time (factor $1/\sqrt{2}$ gives the resolution for one crystal). 3(b) Template fitting for a two electron pile-up event with 4.5 ns time interval. 3(c) Reconstructed beam energy as a function of the true beam energy. The uncertainty on the reconstructed energy is about 3%. 3(d) Energy scale stability of the calorimeter as a function of time.

all 54 calorimeter crystals simultaneously. By comparing the time differences for pulses in different crystals, we found a typical hit time resolution of 25 ps at 3 GeV. Figure 3(c) shows the linearity of the calorimeter in the GeV range. Each entry for the reconstructed energy has a resolution of about 3%. Figure 3(b) shows a pile-up event with 4.5 ns time separation to which a template fit is applied. The template fit is able to resolve such events and to reconstruct accurately the energy and hit time of each electron. Finally, Fig. 3(d) shows the evolution of the system gain as a function of the rate in the detector, which tell us about the intra-fill gain stability systematic. The laser calibration system was used to mimic a realistic fill structure (64 μs life-time decay in intensity with a factor 10^4 decay factor over the 700 μs fill). The laser firing rate was a 100 times the expected rate for the experimental running condition at Fermilab. Under these extreme conditions the gain variation meets the goal with $|\delta G| < 10^{-3}$.

The data acquisition system (DAQ) for E989 is based on the Maximum Integrated Data Acquisition System (MIDAS) software [14]. The DAQ must read out data without dead time from more than 1,300 read-out channels with 12 Hz fills on average 100 Hz at peak). This represent abouts 20 GB/s of data. The on-line processing for the calorimeter data (very large fraction of all the data) uses GPUs processing to only select data of interest, that is, the pulses originated from a particle interacting with the calorimeter crystals. This result for the calorimeter data to reduce the rate from 18 GB/s to

75 MB/s. Data monitoring is also required to ensure on-line and off-line the data quality / integrity. The total anticipated data stored to tape for the experiment is about 2 PB.

The last major system improvement is the tracker system, which will give access to the dynamic of the stored muon beam. There are three tracker stations, each station being made of 8-module 1500-channel straw tracker. Each station is located in front of one calorimeter. The tracker system will allow control of several systematic uncertainties. Within the time window used to count the number of positrons above an energy threshold, some of the stored muons are being lost outside of the storage region due to beam dynamic effect. The energy-time correlation of these lost muons changes the polarization content of the counted positrons over time and thus is a source of systematic uncertainty. The tracker stations will allow monitoring of the lost muons. The tracker system can also address coherent betatron oscillation (CBO). The tune of the closed orbit differs from one. Due to the betatron oscillation and the geometrical acceptance, each calorimeter station will see a different part of the beam turn-by-turn. This affect the counting of the positrons. From the measured trajectory of the decay positron, the tracker system can reconstruct the dynamics of the beam and its CBO motion. An other important systematic has to do with the vertical focusing of the beam. Due to the momentum spread of the beam from the magic momentum, the electrostatic quadrupoles contributes to ω_a at a non-negligible level and need to be corrected for. The tracker system allows to reconstruct the momentum spread of the stored muon beam (or equivalent the frequency or radius distribution) that enters the estimation of the correction. There is also a contribution to ω_a due to the fact that the muon have a small but non-zero vertical component to their velocity.

On a different topic, the tracker system makes possible the measurement of the electric dipole moment (EDM) of the muon by looking at the vertical component of the momentum of the decay positrons. An EDM would introduce a vertical tilt to the ω_a vector resulting in an vertical upper/lower asymmetry for the number of measured positrons. A factor 2 of improvement in the precision is expected with respect to the E821 measurement.

6 Third challenge: ω_p systematic uncertainty

The measurement of the intensity of the magnetic field is the second key measurement to determine the value of a_μ. It is measured in term of the Larmor precession frequency of a free proton:

$$\hbar\omega_p = 2\mu_p|\vec{B}|. \tag{4}$$

The magnet used by E821 is reused for the current experiment. It is a continuous 44.7 m circumference magnet made of 12 30-degree C-shaped iron yokes and superconducting coils (see Fig. 4(a), 4(b)). 5200 Amp circulate through the coils to produce a 1.45 T field. Other important pieces (poles, wedges, top hats...) are part of the magnet to help improving the field uniformity as discussed below. E989 aims to know the magnetic field averaged over running time and the muon distribution to an uncertainty of ±70 ppb. It requires:

1. Producing as uniform magnetic field as possible by shimming the magnet;

2. Stabilizing B in time at the sub-ppm level by feedback, with mechanical and thermal stability;

3. Monitoring B to the 20 ppb level around the storage ring during data collection;

4. Periodically mapping the field throughout the storage region and correlating the field map to the monitoring information without turning off the magnet between data collection and field mapping. It is essential that the magnet not be powered off unless absolutely necessary;
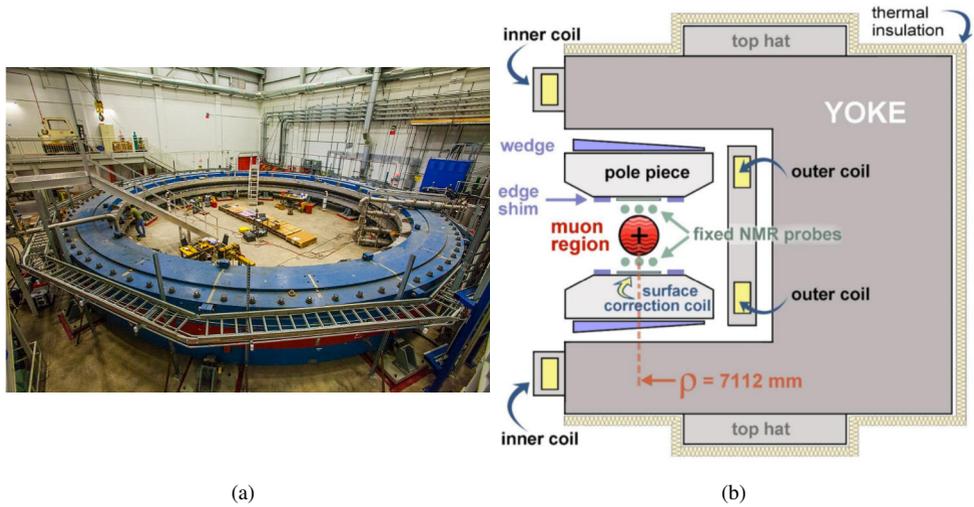

(a)   (b)

Figure 4. 4(a) Storage ring in the experimental hall at Fermilab. 4(b) Sketch of the cross-section of the storage magnet.

    5. Obtaining an absolute calibration of the B-field relative to the Larmor frequency of the free proton.

    Given the required sensitivity, pulsed nuclear magnetic resistance (NMR) techniques are used. Tremendous progress were achieve between October 2015 and August 2016 regarding the passive shimming[1] of the magnet to produce as uniform field as possible (item 1). The first shimming step consisted in minimizing step and tilt discontinuity between adjacent pole pieces by moving the poles pieces adding metal shims under their mounting feet. The second step reduced the quadrupole component of the field. 48 iron top hats which affect the field in a 30 degree section and 864 wedges which affect a 10 degree section were moved through many iteration to reduce field variation around the ring. The last step is consisting in deploying 8,000 thin iron foils which affect 1 degree section of the ring on the pole surface (lower pole surface for the upper pole and vice-versa). Field simulations along with iterating the procedure will allow to reach the desired precision. Figure 5 shows the NMR field scanning performed for the first time in October 2015 along with the most recent scan in August 2016. Figure 5(a) shows the relative difference to the average magnetic field value as a function of the azimuth. The relative difference dropped from ±700 ppm to ±25 ppm with the nominal goal being ±25 ppm. Figures 5(b) and 5(c) show the azimuthally averaged as a function of the transverse coordinates for respectively October 2015 and August 2016. We can see that the ±25 ppm variation with its dipole contribute dropped to ±3 ppm with the main contribution being now the sextupole and octupole components of the field. The nominal goal is ±1 ppm.

7 Conclusion

The Fermilab E989 experiment is on schedule to release its first result (with the BNL E821 statistics) of the measurement of the anomalous magnetic moment of the muon in Spring 2018. The modification

---

[1]Passive shimming refers to the set of mechanical adjustments that are performed during the assembly of the ring and remain fixed during the running period.
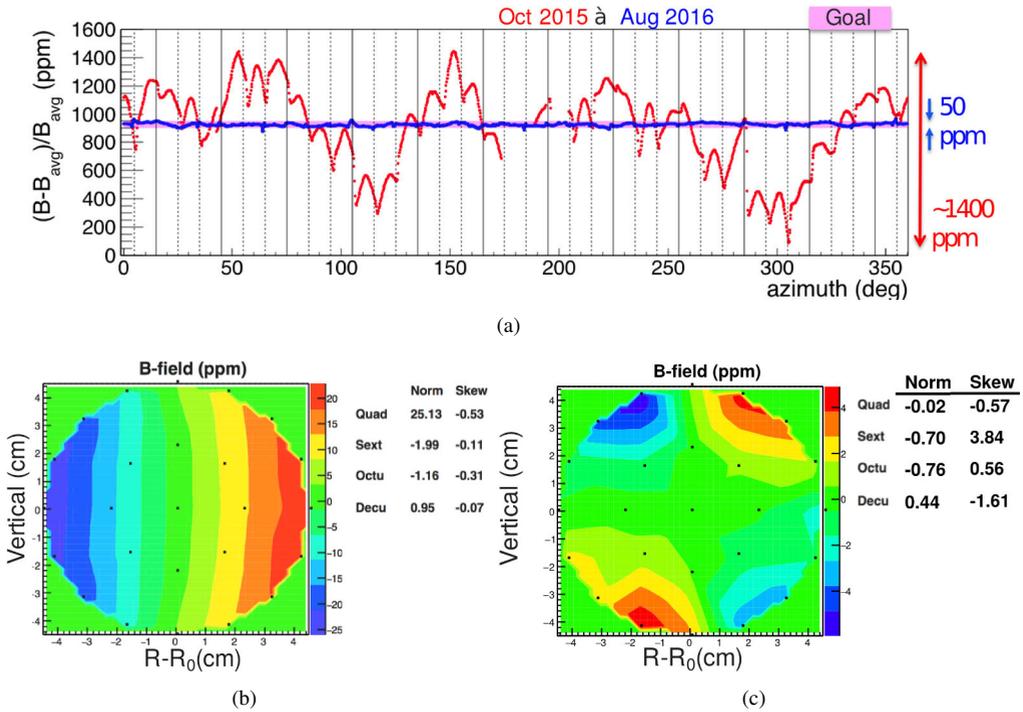

Figure 5. 5(a) Relative difference to the average magnetic field value as a function of the azimuth when the magnet was first powered-on in October 2015 (red), in August 2016 (blue) and the goal (pink). Azimuthally averaged field as a function of the transverse coordinates in October 2015 5(b) and August 2016 5(c).

of Fermilab accelerator complex will be done by Spring 2017 when the commissioning of the storage ring will start. By that time the various detector subsystems will be installed with the ring inside the experimental hall. The passive shimming of the magnet to produce a highly uniform magnetic field is currently well underway and should complete in the following months, leaving the floor open for the active shimming to start. The final result anticipated for 2020 aims to reduce the total uncertainty of the BNL E821 experiment by a factor four.
