Abstract. We introduce an accurate numerical method for the computation of 2D and 3D granular collapse under gravity flows using the $\mu(I)$ rheology. We show that this rheology can capture the two experimentally observed types of spreading and the corresponding scaling laws, and we provide an accurate sensitivity analysis to rheological constants. Finally, we underline the role of time-dependency on the spreading dynamics.

1 Introduction

Granular column collapse under gravity (Fig. 1) is a benchmark problem for several applications from geophysics to industry.

It has been shown experimentally, by Lube et al. [1] for 2D and Lube et al. [2] and Lajeunesse et al. [3] for 3D granular columns of initial aspect ratio $a = h_i/r_i$ (initial height/initial width or radius), that for large enough values of a , the final width or radius r_∞ , reached after spreading, obeys the scaling law $(r_\infty - r_i) / d_i \approx a^{2/3}$ in 2D and $a^{1/2}$ in 3D flows. Moreover, it was shown [1] that the normalized distance-time data (t, x) plot (see Fig. 1) exhibits a universal shape, independently of the grain type (fine or coarse sand, rice, sugar, ...).

For shear flows in the dense granular regime, da Cruz et al. [4] shown, by dimensional arguments on discrete numerical models, that the inertial number $I = |\dot{\gamma}| d \sqrt{\rho_s / p}$ (where $|\dot{\gamma}|$, d , ρ and p are the norm of the strain rate tensor, the grain diameter, the grain density and the pressure) governs the transition between a low friction *quasi-static* regime and a high friction *inertial* regime.

2 Flow model and numerical method

Then, Jop et al. [5] proposed a (computationally lighter) pressure p dependent viscoplastic continuum model called $\mu(I)$, where the extra-stress $\tau_{ij} = (\mu(I)p / |\dot{\gamma}|) \dot{\gamma}_{ij}$ is defined using an effective friction coefficient $\mu(I) = \mu_s + (\mu_F - \mu_s) / (I_0 / I + 1)$ that varies from μ_s (*quasi-static* regime) to μ_F (*inertial* regime) when the inertial number reaches the (material dependent) parameter I_0 . So far, the $\mu(I)$ model has been successfully applied for the prediction of benchmark

steady experimental flows [6]. Concerning complex transient flows of granular column collapse, even though recent papers have shown that discrete numerical simulations can match the experimental scalings [7, 8], few studies have addressed the pertinence of the $\mu(I)$ continuum model in 2D [8] and, to our knowledge, 3D studies are still missing.

In this paper, we study the pertinence of the $\mu(I)$ model to predict the case of 2D and 3D granular column collapse flows. We use a time-dependent regularization algorithm to solve this model using a finite element method, combined with anisotropic mesh adaptation to capture accurately the quasi-static vs. inertial flow zones, and using a variational multiscale method [9].

A Level-Set method, based on self-reinitialization of the signed distance function, aims to capture and follow efficiently the interface between the fluid/air domains.

3 Results

3.1. Column collapse simulations

Our simulations show that the $\mu(I)$ model can reproduce all the qualitative features of the experimentally observed flows (see Fig. 1), such as spreading, front flow acceleration, steady and deceleration phases, as well as a remaining flat top for low aspect ratios and the appearance of surface waves for high aspect ratios. Our computations have been validated using a comparison to 2D continuum and discrete simulations from [8], in particular an accurate deceleration phase is predicted (see Fig. 2).

Moreover, 2D and 3D results show that most of the flow is in a *quasi-static* regime, the *inertial* regime being only reached in a small volume at the front flow. However, this thin and low pressure front flow contributes

significantly to the spreading distance, in the deceleration phase. 2D and 3D initial aspect ratio scaling laws for spreading distance are then quite accurately retrieved: exponents 0.97 and 0.69 in 2D, and exponents 1.00 and 0.54 in 3D (see Fig. 3 and Fig. 4).

3.2. Shear bands

For large friction coefficients μ_s , the $\mu(I)$ model exhibits non-unique solutions at early times of the flow (acceleration phase): mesh dependent short length scale instabilities (shear bands) appear, which is consistent with the theoretical predictions of [10]. However, these instabilities do not subsist during the steady front velocity and deceleration phases.

3.3 Sensitivity to rheological constants

Sensitivity analysis on rheological constants was performed for quasi-static μ_s and inertial μ_F friction parameters, in order to verify the universality (no dependency on grain type) of flow features such as relative spreading vs. aspect ratio, and normalized distance-time.

As shown on Fig. 5, sensitivity to quasi-static friction is of order $\sim 1/\mu_s$ for low and high aspect ratios. The whole final surface shape is significantly affected, as shown on Fig. 6, where the final global slope is strongly dependent on μ_s .

Sensitivity to the inertial friction parameter is subtler (of order $\sim 1/\mu_F$), but noticeable (see Fig. 7). As expected, the final surface shape is changed only at larger radii (see Fig. 8), as it was pointed out that the inertial regime is reached at the front flow.

An additional sensitivity, not discussed in experimental papers, is due to the time-dependency. Indeed, the time scale of the flow being $\sim \sqrt{h_i/g}$ (where g is the gravity acceleration), a collapse from a larger initial height h_i , for fixed materials properties and aspect ratio, should benefit to the inertial regime, as the strain rate would scale as $\sim 1/\sqrt{h_i}$ and the pressure as $\sim h_i$. Consequently, the inertial number would scale as $\sim 1/h_i$, which would mean a lower friction for larger columns, keeping the aspect ratio constant. A similar effect on inertial number can be deduced by considering the grain diameter (which is an internal length scale not taken into account in the experimental results) rescaled by the column height. Indeed, our computations show that when increasing the initial height, one still get a power law $\sim a^{1/2}$ with aspect ratio, but also a larger relative spreading (see Fig. 4, red dots).

4 Conclusion

A quantitative dependency of granular collapse flow features to material (rheological) constants was computed in the light of the $\mu(I)$ rheology. This gives complementary information to experimental literature, which reported these features in log plots, where a subtle but real sensitivity exists. Moreover, we have pointed out that the relative spreading should be time-dependent. This property will be investigated in a future experimental study.

Fig. 1. $\mu(I)$ computation of the shape of a granular column at time $t = 20\%$, 40% , 60% and 80% of total collapse, for an initial ratio $a=7$; rheological parameters were taken from [5]
