Optical laser radiation

Many configurations have been proposed to use high-power laser radiation for acceleration of the charged particles [1]. Required power density for such experiments varied from 10^{18} W/cm² up to 10^{20} W/cm². For example, X-rays of MeV energy have been produced by accelerated plasma electrons when laser beam with intensity of 5*10^{18} W/cm² was focused on tantalum sheet. Energy of these X-rays was high enough to initiate a set of nuclear reactions, which have been registered experimentally [2].

We investigate an influence of coherent electromagnetic radiation on different types of radioactive decay. Our experiments indicate that some nuclear reactions can be initiated even at laser beam intensity about 1*10^{12} W/cm². The key feature is the presence of metallic (chemically inactive Au as a rule) nanoparticles. In plasmon resonance regime the wave field near nanoparticles can be concentrated up to the necessary level. Layout of the typical experiment is shown on fig. 1.

![Fig. 1. Layout of the experiment on irradiation of water solution of the radioactive salt by the medium-power laser in presence of the metallic nanoparticles](image)

We use several types of optical and near-infrared lasers – Cu vapor, femtosecond Ti:sapphire, 90-ps Nd:YAG, 350-ps Nd:YAG, 10-ns Nd:YAG. Their pulse energy varied from 0.1mJ up to 40 mJ, repetition rate varied from 10 Hz up to 20 kHz. Power density in focal region without influence of the nanoparticles varied from 1*10^{11} W/cm² up to 1*10^{12} W/cm². Nanoparticles being used in our experiments are produced by laser ablation by metal target in the water.

We have observed partial Hg transmutation into Au inside heavy water D₂O [3]. Laser irradiation in presence of Au nanoparticles initiates the decay of ²³²-Th [4]. Very exciting result was a significant (up to 50%) decrease of gamma-activity of ²³⁵U and ²³⁵U series after laser irradiation in presence of beryllium nanoparticles [5].

![Fig. 2. ²³⁴Th activity during several sessions of laser irradiation of UO₂Cl₂ water solution in presence of Au nanoparticles as the laser wave concentrators. ¹³⁵Cs is a reference sample](image)

Microwave radiation

There are some similar experiments in microwave and radiofrequency regions. 3 GHz radiation caused increasing the ⁵¹Cr activity at 1% [6]. 0.07% of the ¹³⁷Cs activity growth was registered during irradiation of the sample by 4.1 MHz and 1.55 MHz radiation with a maximum power of 50 kW [7]. Our experiment using 30 GHz FEM shows about 1.5% variation of the ¹⁵²Eu activity [8]. In all these experiments there were no special measures to increase the power density.
Field concentrators in microwave experiment

We assume that all changes in the rate of the radioactive decay were caused by the charged particles accelerated in the plasma, produced in focal region in presence of field concentrators (metal nanoparticles). We have in mind that the power density about $1 \times 10^{18}$ W/cm$^2$ is enough to produce some types of nuclear reaction without special field concentrators. Estimation of the maximal energy of the proton inside the electromagnetic wave with wavelength $\lambda$ and intensity $I$ can be done by [9]:

$$E_{\text{max}} = 3.6 \sqrt{\frac{\lambda}{10^{18}}} I,$$

where $E_{\text{max}}$ is in MeV, $\lambda$ in microns, $I$ in W/cm$^2$. Indeed, the wave with length of 1 micron and intensity of $1 \times 10^{18}$ W/cm$^2$ can accelerate protons up to 3.6 MeV, which is more than the threshold of many nuclear reactions. In our experiments with power densities of $1 \times 10^{12}$ W/cm$^2$ the presence of field concentrators (nanoparticles) can increase the field intensity up to $10^5$ and (nanoparticles dimers) to $10^6$ times.

![Diagram of proposed layout of the experiment on the RF irradiation of the radioactive sample. Metal sawdust should be the RF field concentrators.](image)

Let us estimate the necessary rate of field concentration in microwave region. For wavelength of 1 cm (10$^4$ microns) the desired proton energy of 3.6 MeV requires the field intensity of $1 \times 10^{10}$ W/cm$^2$. The diffraction limits the area of focal spot by 1 cm$^2$, so we need or 10 GW radiation source, or 10 MW radiation source and $1 \times 10^4$ times field concentrators. For microwave region the role of the field concentrators can play metal sawdust. The layout of proposed experiment is shown on fig. 4.
