**Abstract.** Stars originate by the gravitational collapse of a turbulent molecular cloud of a diffuse medium, and are often observed to form clusters. Stellar clusters therefore play an important role in our understanding of star formation and of the dynamical processes at play. However, investigating the cluster formation is difficult because the density of the molecular cloud undergoes a change of many orders of magnitude. Hierarchical-step approaches to decompose the problem into different stages are therefore required, as well as reliable assumptions on the initial conditions in the clouds. We report for the first time the use of the full potential of NASA *Kepler* asteroseismic observations coupled with 3D numerical simulations, to put strong constraints on the early formation stages of open clusters. Thanks to a Bayesian peak bagging analysis of about 50 red giant members of NGC 6791 and NGC 6819, the two most populated open clusters observed in the nominal *Kepler* mission, we derive a complete set of detailed oscillation mode properties for each star, with thousands of oscillation modes characterized. We therefore show how these asteroseismic properties lead us to a discovery about the rotation history of stellar clusters. Finally, our observational findings will be compared with hydrodynamical simulations for stellar cluster formation to constrain the physical processes of turbulence, rotation, and magnetic fields that are in action during the collapse of the progenitor cloud into a proto-cluster.

### 1 Introduction

Most of the star formation in the Galaxy is occurring within massive giant molecular clouds [1]. Giant molecular clouds are expected to form hundred of thousands of stars that can originate stellar clusters if the system is able to remain gravitationally bound well beyond its formation phase. This shows that investigating the early dynamical evolution of the molecular clouds is crucial for understanding the star and planet formation processes at different epochs and by taking into account the diversity of environments in the Galaxy [2, 3]. However, the star forming regions are obscured by dust, hence direct observations are limited to the infrared and radio bands. Stellar clusters, which are born embedded to giant molecular clouds, therefore represent important benchmarks to test stellar and planetary formation, and stellar evolution theories. Open clusters in particular generally contain a small amount or no interstellar medium, which makes them well suitable for studies involving a broad range of wavelengths other

than the infrared and radio ones. In addition, conversely to globular clusters, stars in open clusters are sparse enough, with a density of at least  $1 M_{\odot} \text{pc}^{-3}$ , thus providing the opportunity to perform detailed analyses on individual stellar members. The great advantage of this approach is that the stars in a cluster — as opposed to field stars that often originate from the dissolution of small stellar systems — can preserve the signature of the initial conditions of the progenitor cloud.

Little is known on the role of angular momentum on the early stage formation of stars in open clusters. It is believed that molecular clouds satisfying the Jeans instability undergo a gravitational collapse in which the internal motions are strongly influenced by turbulence [4]. This implies that the angular momentum from the progenitor gas cloud cannot leave any significant imprint of their action in the resulting stars of the cluster. From a theoretical point of view, if the angular momentum vector of the cloud is transferred to the individual pre-stellar cores then rotation and possibly magnetic fields could be responsible of guiding the gravitational accretion of mass along preferential

directions in space. For understanding this aspect, reliable measurements of the space orientation of the stellar-spin axis are required. Previous analyses conducted on young open clusters support no evidence of stellar-spin alignment [5], but they relied on a combination of measurements for stellar rotational periods from light curves, projected equatorial velocities from spectroscopy, and stellar radii based on the cluster distance. As a result, the adopted methodology could be prone to significant systematics, and it is not applicable for distant and old populations of stars, whereas the required primary information will lack.

Asteroseismology, the study of stellar oscillations, has proven to be a powerful tool to extract direct information on the stellar interiors, and in particular on the stellar angular momentum vector, thus allowing for accurate and detailed results, especially in the case of red giant stars [6]. Red giants are low- and intermediate-mass stars that have evolved off the main sequence to settle in either a hydrogen-shell-burning or helium-core-burning phase of the stellar evolution. Many red giants exhibit stellar oscillations that can be analyzed through a Fourier spectrum of the light curve. Such a Fourier spectrum contains a regular pattern of tens and sometimes more than a hundred of radial and non-radial stellar oscillation modes [7]. Each oscillation mode can be identified by means of an angular degree  $l$  and an azimuthal number  $m$ , the latter related to the degeneracy lifted by the stellar rotation to form a multiplet of  $(2l + 1)$  components [8, 9]. The dipolar ( $l = 1$ ) mixed modes [10] are the most suited for measuring the orientation of the spin axis.

## 2 Data analysis & results

Here we investigate 48 oscillating red giant members of the open clusters NGC 6791 and NGC 6819 [11–13], with masses spanning from 1.1 to 1.7  $M_{\odot}$  [14]. Both clusters are old, with NGC 6791 one of the oldest known in our Galaxy [15]. Despite their distance (on galactic scales up to  $\sim 4$  kpc), thanks to the high luminosity of the red giants, the individual stellar members could be monitored by the photometric space mission NASA *Kepler* for a period of about 4 years. By performing detailed asteroseismic analyses on each star [16–20], we obtain a total of about 380 rotationally split dipolar mixed modes — identified from a set of more than 3900 oscillation modes — and we use them to measure the spin inclination angles.

The analysis of the rotationally split dipolar mixed modes shows that about 70% of the stars in each cluster has a strong preferential spin orientation, with inclination angles between  $20^{\circ}$  and  $30^{\circ}$ . This is contrary to what would be expected by assuming a uniform 3D distribution of spin vectors, where most of the inclination angles would then be found close to  $90^{\circ}$ . The spatial distribution of the stars also guarantees that they adequately sample the observed spherical morphology of the two stellar clusters.

Existing N-body simulations for old open clusters [21] show that the stellar angular momentum can influence the evolution of colliding stars and of the orbital configurations of multiple stellar systems, e.g. the orbital eccentricities and periods of binaries. In the case of single stars we

instead observe only a spin down over time [22]. Because of the larger average distances among the star members of an open cluster, the N-body interactions cannot produce any appreciable effect on redistributing stellar spin inclinations and yielding a spin alignment even for timescales of several Gyr. As a consequence, the spin alignment that is observed in the stars of our sample should have a different origin, linked to the formation epoch of the cluster.

We have performed 3D hydrodynamical simulations that reproduce the collapse of a dense molecular cloud forming a proto-cluster [23]. The simulations show that when we consider a cloud dominated by turbulent kinetic energy,  $E_{\text{tur}}$ , over that of global rotation,  $E_{\text{rot}}$  (yielding the condition  $E_{\text{rot}}/E_{\text{tur}} < 1$ ), no significant stellar spin alignment is produced in the final pre-stellar cores and the distribution of spin inclinations resembles that of a uniform orientation in 3D space. The scenario becomes comparable to that of our observations when  $E_{\text{rot}}/E_{\text{tur}} \approx 1$  instead. In addition, when considering masses below  $0.7 M_{\odot}$ , even an energy equipartition between rotational and turbulent kinetic energy is not able to produce a significant spin alignment in the resulting pre-stellar cores.

## 3 Conclusion

Our results indicate that a mass above  $0.7 M_{\odot}$ , accreted into a pre-stellar core from the progenitor molecular cloud, would be required in order to allow the cloud's average angular momentum to be transferred from the scale of the molecular cloud to those of individual stars. At least 50% of the cloud's rotational kinetic energy can be responsible of efficiently aligning the spin axes within the stellar members of a cluster. Therefore, the two open clusters NGC 6791 and NGC 6819 are likely to be originating from a formation process that involved a dense collapsing molecular cloud with a strong rotational energy component. Through the measurement of stellar spin inclinations for stars with masses comparable to that of our Sun and belonging to open clusters we can obtain information on the initial energy budget of the progenitor molecular cloud, its global rotation, and the efficiency by which the cloud's averaged angular momentum is transferred to the individual stellar members of the clusters. This will lead to the exploration and reconstruction of the dynamical evolution of galactic star forming regions that have originated clusters with ages up to several Gyr.
