Abstract. One of the main ingredients of nuclear astrophysics is the knowledge of the thermonuclear reactions responsible for powering the stellar engine and for the synthesis of the chemical elements. At astrophysical energies the cross section of nuclear processes is extremely reduced by the effect of the Coulomb barrier. The low value of cross sections prevents their measurement at stellar energies on Earth surface and often extrapolations are needed. The Laboratory for Underground Nuclear Astrophysics (LUNA) is placed under the Gran Sasso mountain and thanks to the cosmic-ray background reduction provided by its position can investigate cross sections at energies close to the Gamow peak in stellar scenarios. Many crucial reactions involved in hydrogen burning has been measured directly at astrophysical energies with both the LUNA-50kV and the LUNA-400kV accelerators, and this intense work will continue with the installation of a MV machine able to explore helium and carbon burnings. Based on this progress, currently there are efforts in several countries to construct new underground accelerators. In this talk, the typical techniques adopted in underground nuclear astrophysics will be described and the most relevant results achieved by LUNA will be reviewed. The exciting science that can be probed with the new facilities will be highlighted.

Nuclear Astrophysics in underground laboratories: the LUNA experiment

duction in the region below 3 MeV in the gamma spectrum can be achieved by implementing a shielding made by copper and lead [10, 11]. A comparison between two gamma spectra acquired with the same detector in surface and at LNGS is shown in Figure 1. In the figure, the detector was also shielded by few cm of OFHC copper and 25 cm of low level background lead when placed in the underground laboratory to obtain almost 4 order of magnitude reduction in the γ-ray background below 3 MeV [10]. A review of the results achieved by the LUNA collaboration will be presented in this paper combined with a discussion on the future projects for nuclear astrophysics in underground with a MV accelerator.

1 Solar Hydrogen Burning

Hydrogen burning in the Sun proceeds mainly by the proton-proton chain (pp-chain, Fig. 2), with a 0.8% contribution from the carbon-nitrogen-oxygen cycle (CN cycle) [12]. The basic processes are by now well understood, leading to the so-called standard solar model [13] that explains both helioseismological data and neutrino observations.

LUNA started its work studying the \(^3\)He(\(^3\)He,2p)\(^4\)He reaction. This is a key reaction of the hydrogen burning proton proton chain and at the beginning of the seventies it was believed to exist a possible resonance in the \(^3\)He(\(^3\)He,2p)\(^4\)He Gamow peak that could have explained the low measured neutrino flux measured by the Homestake experiment [14]. The experiment was performed at the LUNA1 accelerator by using a windowless gas target, filled with \(^3\)He, and eight 1 mm thick silicon detectors of 5x5 cm² area. The cross section was measured in an energy range from 16.5 to 24.4 keV, totally covering the Gamow peak for the Sun [15, 16]. The debated resonance [17, 18] was not observed, ruling out the possible nuclear explanation of the so called Solar Neutrino Problem.

The neutrino fluxes emitted by the Sun are strictly correlated with other nuclear processes involved in the hydrogen burning. In particular, the \(^3\)He(α,γ)\(^7\)Be reaction reaction controls the \(^7\)Be and \(^8\)B neutrinos and it is also fundamental for the production of \(^7\)Li during the Big Bang Nucleosynthesis (BBN). The \(^4\)He(α,γ)\(^7\)Be reaction was studied at the LUNA2 accelerator by using both the gamma prompt detection [19, 20] and the activation techniques [21, 22] finding a perfect agreement within the two methods. This result was important not only to reduce the systematics, but also to solve the discrepancy previously shown in experiments based on the two different techniques.

The \(^14\)N(p,γ)\(^15\)O reaction is the bottleneck of the CN cycle and therefore the \(^14\)N and \(^15\)O neutrinos are controlled by this reaction. The LUNA collaboration started the study of this reaction by performing two different experiments: one characterised by solid target setup and HPGe detector. This kind of setup allows to study separately all branchings and to perform R-Matrix analysis [23, 24]. A second setup, made of a windowless gas target and a 4π-BGO detector, was used to measure the total cross section in a wide range of energy (down to 70 keV in the center of mass) thanks to the high efficiency provided by the BGO [25, 26], totally covering the nova explosion scenario with experimental data. In those experiments the cross section was found lower by a factor of 2 with respect to the reported value in NACRE [27] with considerably effects on the neutrino fluxes from the Sun and the age of globular clusters[28].

Recently, a discrepancy between helioseismology and the new metal abundances (i.e. the amount of elements different from hydrogen and helium) that emerged from improved modelling of the photosphere has been reported [29]. This so called Solar Composition Problem [12] can be addressed by the possibility to detect the CNO neutrino with new experiment and to parametrize with extreme precision the Solar models. For this reason the \(^14\)N(p,γ)\(^15\)O cross section is requested to be known with a precision of 5%, almost factor of two lower than what reported in the last database [30]. In order to reduce this nuclear uncertainties in the solar model a new measurement was performed at LUNA by measuring three energy point above the 259 keV resonance and leading to and extrapolated...
value $S_{114}(0)=1.57\pm0.13$ keV barn [31, 32]. Another recent measurements has been performed at the Notre Dame University [33] at higher energies obtaining an extrapolated value higher than the one reported by LUNA. In this context a new measurement is requested in a wide energy range and it will be done as first measurement of the future LUNA MV accelerator, which will cover an energy range from 3 MeV down to 200 keV with an unique set of data, leading to precise extrapolation.

1.1 The other CNO cycles

The $^{15}\text{N}(p,\gamma)^{16}\text{O}$ is the link from the first to the second CNO cycle and it was studied intensively at the LUNA accelerator. Data acquired with a gas target setup and natural nitrogen (which contains a 0.37% of $^{15}\text{N}$) to study the $^{14}\text{N}(p,\gamma)^{15}\text{O}$ reaction were analysed to determine the $^{14}\text{N}(p,\gamma)^{15}\text{O}$ cross section in the energy range from 230 keV down to 90 keV in the center of mass[34]. After that, two new experiments were performed by using $^{15}\text{N}$ enriched solid targets [35, 36]. The LUNA data cover totally the Gamow peak in nova explosion where the $^{15}\text{N}(p,\gamma)^{16}\text{O}$ is mainly important and the cross section was found to be lower than a factor of 2 with respect what reported in the NACRE database [27]. This leads to a reduction of $^{16}\text{O}$ produced by nova of a 40%.

The $^{17}\text{O}(p,\gamma)^{18}\text{F}$ reaction was investigated from 2011 to 2013. The ratio between the reaction rates of $^{17}\text{O}(p,\alpha)^{14}\text{N}$ ($Q = 1.2$ MeV) and $^{17}\text{O}(p,\gamma)^{18}\text{F}$ ($Q = 5.6$ MeV) channels is one of the most important parameters for the galactic synthesis of $^{17}\text{O}$, the stellar production of radioactive $^{18}\text{F}$, and for predicted O isotopic ratios in pre-molar grains [37, 38].

Since the $^{18}\text{F}$ is a radionuclides with a half life of $\approx 110$ min, the cross section has been determined both by detecting the prompt gamma rays and by counting the 511 keV $\gamma$s emitted by the $^{18}\text{F}$ decay. The results are in perfect agreement reducing considerably the systematics [39]. New results on the non resonant component and on the 183.3 keV resonance have been obtained ($\omega\gamma = (1.67 \pm 0.12)\mu$eV [39, 40]) reducing the uncertainties of isotopes production in nova explosion models to a 10% level [40]. The very low uncertainty obtained in this experiment was possible thank to an intensive study of the target, realised and tested directly by the LUNA group with ion beam analysis and secondary induced mass spectroscopy techniques [41].

An intense study on the $(p,\alpha)$ channel has been followed: a detection system composed by eight silicon detectors was used in this study to detect with high efficiency the $\alpha$ particles emitted. This experimental system is described in [42] and was used to measure directly the low energy resonance at 64.5 keV finding an $\omega\gamma = (8.7 \pm 1.2_{stat} \pm 0.6_{syst})\mu$eV for the bare nuclei [43]. The LUNA value is a factor of 2 higher than what previously reported in literature [44, 45] bringing to important consequences in the AGB [46] and, in particular, in finding a possible explanation for the production sites of pre-solar grains enriched in $^{17}\text{O}$ [47].

1.2 The Ne-Na and Mg-Al cycles at LUNA

The nucleosynthesis in the neon sodium cycle occurs via many reactions. In particular, the uncertainty on the $^{22}\text{Ne}(p,\gamma)^{23}\text{Na}$ dominates the uncertainty of the entire cycle. As a matter of fact this reaction has several resonances below 400 keV and many of them were only given as upper limits based on indirect measurements. In particular, the databases [27, 48] reported a discrepancy of a factor one thousand. A fully shielded setup has been implemented [11] to observe for the first time three resonances and to improve the upper limits for other three resonances [49, 50]. Finally, an updated reaction rate has been obtained, which is significantly higher than the one given in the most recent compilation of reaction rates [48]. As a consequence, new values for the ejected mass of $^{22}\text{Ne}$ and $^{23}\text{Na}$ in thermally pulsing AGB stars have been obtained with much reduced uncertainties [51].

The study of the CNO cycles is the natural precursor for the hydrogen burning in Mg-Al cycles. The problem of the $^{26}\text{Al}$ production is one of the most interesting cases [52]. LUNA measured precisely several resonances for $^{24,25}\text{Mg}(p,\gamma)^{26,27}\text{Al}$ in order to reduce the uncertainties on those reactions as requested in the astrophysical models [53, 54]. The impact of the LUNA results is discussed in details in a recent work [55].

2 Big Bang Nucleosynthesis

The $^3\text{He}(\alpha,\gamma)^7\text{Be}$ reaction has an important role in solving the problem of the Spite plateau [56]. LUNA measured this reaction in the Gamow peak for Big Bang Nucleosynthesis reducing the uncertainties to 3% overall. Another problem concerning lithium isotopes as been raised recently: the $^6\text{Li}$ has been measured to be 3 order of magnitude higher than what expected in BBN [57]. While it is generally believed that $^6\text{Li}$ is produced by cosmic-ray spallation over the lifespan of the universe, the $^6\text{Li}$ observations in halo stars seem to suggest a primordial origin instead. For $^6\text{Li}$ production in the Big Bang, the main nuclear physics unknown is the $^3\text{H}(\alpha,\gamma)^4\text{Li}$ reaction rate. The setup used to study this reaction is already described in details [58]. The scattering chamber was filled with high purity deuterium gas. The accelerated deuterium particles, after Rutherford scattering with the $\alpha$-beam, interact with the gas itself producing the two reactions: $^3\text{H}(d,n)^4\text{He}$ and $^2\text{H}(d,p)^3\text{H}$. In particular, the neutrons emitted by the $^2\text{H}(d,n)^3\text{He}$ were responsible for a high beam induced background in the $\gamma$-spectrum. A long and detailed study of this background was required in order to perform the analysis of the data [58–60].

3 Science case for a future higher-energy accelerator underground

Recent advances in astronomy and astrophysics require nuclear data at energies that are higher than the high-energy limit of LUNA2.

To explore the helium and carbon burnings a new MV accelerator will be installed at LNGS during the 2018.
With the new accelerator, a long list of reactions will be studied. A first 5 years program is detailed discussed in [61]. The first reaction will be the $^{14}\text{N}(p,\gamma)^{15}\text{O}$. The solar composition problem has been already addressed above and recently a new measurement has been performed at high energy founding discrepancies with the LUNA data [33]. With the new LUNA MV it will be possible to cover with an unique set of data a wide energy range from 2 MeV down to the LUNA2 energies, allowing to reduce the systematics down to the goal of 5%.

Another important open issue of nuclear astrophysics is the neutron source reactions. In particular the $^{13}\text{C}(\alpha,n)^{16}\text{O}$ and $^{22}\text{Ne}(\alpha,n)^{25}\text{Mg}$ reactions. They are responsible for the production on neutrons involved in the slow neutron capture process, called the astrophysical s-process. Whereas those reactions are the subject of intensive experimental study [62, e.g.,] so far the reactions actually producing the neutrons have not yet been measured in the relevant energy range since they should be addressed by an underground accelerator.

The $^{12}\text{C}^{+12}\text{C}$ is the trigger of the carbon burning and is a key reaction to predict the final stage of a star. It determines which is the mass required to a star to ignite this burning stage. In addition, this reaction also affects the outcome of type Ia supernovae. Both the two channels (proton and $\alpha$) have never been studied down below 2 MeV. At the LUNA MV it will be possible to measure the cross section down to 1.7 MeV very close to cover the whole Gamow peak.

A third topic is to complement some of the proton- and $\alpha$-capture reactions studied at the LUNA2 accelerator at higher energy. Such a continuation is particularly important for the Big Bang reactions $^{3}\text{He}(\alpha,\gamma)^{7}\text{Be}$ and $^{2}\text{H}(\alpha,\gamma)^{6}\text{Li}$, where the present LUNA2 400 kV machine can only cover the lower part of the relevant energy region.

4 Future underground accelerator facilities

Based on the successes of the LUNA collaboration, around the world several efforts are underway to install high-current, stable-beam accelerators in underground sites. LUNA MV project was started in order to install a 3.5 MV machine in the underground laboratories of Gran Sasso. The new accelerator has already been financed by the Italian government and it should be installed in the next year at the Gran Sasso Laboratory. The synergy between the existing LUNA2 and the new LUNA MV accelerator will allow to perform reaction studies in a wide range of energies with complete understanding of the setups involved. Other facilities have been proposed for installing an accelerator in deep underground laboratory in US [63] and in China [64]. Another project is under discussion at the Canfranc underground laboratory in the Pyrenees, Spain. As part of a staged approach, even an accelerator laboratory in a shallow-underground facility such as Felsenkeller (Dresden, Germany) is under consideration.

At present, the existing 400 kV LUNA2 machine continues its scientific program outlined in [65]. The next few years will show where this highly successful approach will eventually be complemented by one or more higher-energy accelerators underground. The technique is sufficiently mature to address not only the data needs of the astrophysics community, but it has the potential to benefit also the astroparticle and other communities.

Acknowledgments

The work at LUNA is carried out in the framework of the LUNA collaboration; see e.g. Ref. [43] for an author list.
