On the Hadronic light-by-light contribution to the muon $g - 2$

Johan Bijnens$^{1, a}$

$^1$Department of Astronomy and Theoretical Physics, Lund University, Sölvegatan 14A, SE22362 Lund, Sweden

Abstract. This talk is about the hadronic light-by-light contribution to the muon anomalous magnetic moment, mainly our old work but including some newer results as well. It concentrates on the model calculations. Most attention is paid to pseudo-scalar exchange and the pion loop contribution. Scalar, $a_1$-exchange and other contributions are shortly discussed as well. For the $\pi^0$-exchange a possible large cancellation between connected and disconnected diagrams is expected.

Figure 1. HLbL contribution to the muon anomaly $a_\mu$. The crossed circle indicates the strong interaction part.

1 Introduction

This talk is mainly an update of my talk from two years ago [1] and has thus a very large overlap with it. In addition, this writeup should be read together with a number of other contributions to this and the previous workshop [2]. A more general introduction to the muon anomaly $a_\mu = (g_\mu -2)/2$ was given in the talk by and Knecht [3]. An alternative method to obtain the hadronic light-by-light-contribution (HLbL) shown in Fig. 1 was discussed in the talk by Colangelo [4]. The present status of the lattice calculations of the same quantity were discussed by Lehner [5] and Nyffeler [6].

The main reason for this sessions is the measurement of the muon anomalous magnetic moment of [7] and the discrepancy with the standard model prediction and the new measurements in progress at Fermilab and under development at J-PARC. Reviews of the theory can be found in [8–10]. More references can be found in the remainder of this talk and the talks mentioned above. The present best estimate of the HLbL is $(11 \pm 4) \times 10^{-10}$ [8, 10] or $(10.5 \pm 2.6) \times 10^{-10}$ [9]. The main difference is an estimate of the errors which is always somewhat subjective. A new report with the aim of getting a consensus is under way as discussed in [11].

In this talk I will concentrate on the work done a long time ago [12–14] as well as some newer work on the pion loop [15]. I will also discuss more recent contributions about the pseudo-scalar exchange and quark-loop. I do not present a new final overall number but will argue that a good estimate for the pion-loop contribution is $-(2.0 \pm 0.5) \times 10^{-10}$.

An often asked question is why one cannot simply calculate the hadronic parts in Chiral Perturbation Theory (ChPT). ChPT is an effective field theory approximation to QCD valid at low energies. Since the muon has a low mass, at first sight $a_\mu$ should be a perfect quantity to calculate in ChPT. This is not true both for HLbL and the hadronic vacuum polarization contribution (HVP) there are integrals over all photon momenta present. The hadronic part is thus not only at low-energies. The lowest-order prediction for both HVP and HLbL is the same as for scalar QED and is finite. However, higher orders require a higher dimensional counterterm that is precisely the same as the muon Pauli term. We are thus left without a prediction beyond lowest order in ChPT. However, ChPT can (and should be) used to put as many constraints as possible on the underlying hadronic quantities.

We thus need to go beyond ChPT since we need high energies and beyond perturbative QCD since we need low energies for the hadronic quantities. The main options are experiment, dispersion relations, lattice QCD and models. For the HVP contributions models only play a role in understanding the results from the other approaches. For HLbL, we have not quite reached that stage but important progress is being made as discussed by Colangelo, Lehner and Nyffeler. In the future, the main roles for models will be estimating the contributions that are not included in the systematic approaches.

The requirement for a model calculation is simple to formulate “do as well as you can.” That means constraining your model as much as possible from experiment via measured states, form-factors and scattering processes and from theory by including as many long-distance constraints from ChPT and short-distance constraints from...
perturbative QCD. One should also use “common sense” in varying model parameters, making sure your model is general enough to describe what you need to describe and if different regions are treated differently consistency between them should be checked.

An overview of general properties of the underlying four-point functions and the early calculations is in Sect. 2. Sect. 3 discusses the numerically largest contribution, pseudo-scalar meson exchange. Next I discuss the pion-loop contribution in some detail since here I have new results [15]. The quark-loop, which has rather large theoretical errors, is discussed in Sect. 5. The remaining leading large \( N_c \) exchanges are scalar, discussed in Sect. 6, and \( a_1 \)-exchange, Sect. 7. The \( \pi \)-loop contribution is treated in more detail since there is where I have some new results to present. Details are in Sect. 4. Conclusions and some possible future directions are given in the last section.

## 2 General properties and early work

The underlying object is the four-point function \( \Pi^{\mu\nu\rho\sigma}(p_1, p_2, p_3) \) of four electromagnetic vector currents. We really need only the derivative w.r.t. \( p_3 \) at \( p_3 = 0 \),

\[
\frac{\delta \Pi^{\mu\nu\rho\sigma}(p_1, p_2, p_3)}{\delta p_{3\mu}} \bigg|_{p_3=0}.
\]

\( \Pi^{\mu\nu\rho\sigma}(p_1, p_2, p_3) \) has in general 138 Lorentz structures which reduces to 43 gauge-invariant structures. Note that in four dimensions there really are 2 less, 136 and 41 [16]. Of the 138 more general structures 28 [15] actually contribute (improving the 32 estimate of [13]). Each of these functions depends on \( p_1^2, p_2^2, q^2 \) and before the derivative also on \( p_2^2, p_1, p_3, p_2, p_3 \). This should be compared with the lowest order hadronic vacuum polarization where there is one function of one variable. An alternative split is using the helicity amplitudes for off-shell photon-photon scattering as used in the dispersive work by Colangelo and collaborators [4]. The choice of basis is definitely not unique and different choices are appropriate for the different approaches.

After setting \( p_3 \to 0 \) the loop integrals over the photon momenta is 8 dimensional. Three of these integrations are trivial and using Gegenbauer polynomial methods two more can be done [10, 15, 17]. So, after having a model or a computation of \( \Pi^{\mu\nu\rho\sigma}(p_1, p_2, p_3) \) there is a triple integral over \( p_1^2, p_2^2, q^2 \) left. The components and their derivatives become multiplied with functions of \( p_1^2, p_2^2, q^2 \) examples of which are in [10, 17] and the full results can be found in [15]. In the work I have been involved in we did the relevant integrations in Euclidean space, i.e. with \( p_1^2, p_2^2, Q^2 = -p_1^2, -p_2^2, -q^2 \) always positive.

How models actually contribute to the muon anomaly \( a_\mu \) can be studied by rewriting the integral over \( P_1^2, P_2^2, Q^2 \) in the form [8]

\[
a_\mu = \int dl_p dl_{\rho} dl_{\sigma} d_P^{1L} = \int dl_p dl_{\rho} dl_Q d_Q^{1LQ},
\]

with \( l_p = (1/2) \ln \left( \frac{P^2}{\text{GeV}^2} \right) \). The reason for choosing the logarithm is that this way it is easiest to see which momentum region contributes. Alternatively one can integrate each momentum up to a cut-off \( \Lambda \).

One should remember that the different contributions are usually defined within a given model or approach. What is included under the same name can therefore differ and one should be careful when drawing conclusions from comparing calculations.

The underlying problem is that the integration over photon momenta \( p_1, p_2 \) in the diagram in Fig. 1 contains both low and high momenta and mixed cases. Double counting is thus a serious issue when using both quark and hadron contributions. In Ref. [18] a partial solution was found by using chiral \( p \) and large \( N_c \) counting to distinguish different contributions. This does not fully solve the double counting issue but it is a good start. This suggestion was followed by two groups doing a more or less full evaluation of the HLLB. Kinoshita and collaborators [19–21] (HKS) used meson models, did the pion-loop using the hidden local symmetry model for vector mesons and the quark loop with simple vector meson dominance (VMD). Calculations were performed in Minkowski space. The one I was involved in [12–14] (BPP) tried to use a consistent model, the extended Nambu-Jona-Lasinio (ENJL) model as in [22, 23], as much as possible but adjusted using measured form-factors and QCD constraints. The calculations were done in Euclidean space. In fact, these two are still the only existing full calculations, but many parts have been evaluated using other approaches since then.

The main observations were:

- The largest contribution is \( n^0 \) and \( \eta, \eta' \) exchange/pole. Be aware that exchange and pole or not precisely the same. Most estimates of this part are in reasonable agreement as discussed in Sect. 3.
- The pion loop can be sizable, with a large difference between the two evaluations and even larger numbers have been proposed. Further discussion is in Sect. 4.
- The other contributions are smaller but there are many and cancellations are present.
- Final numbers:
  - BPP: \( (8.3 \pm 3.1) \times 10^{-10} \)
  - HKS: \( (8.96 \pm 1.54) \times 10^{-10} \).

## 3 \( n^0 \)-exchange

The single largest numerical contribution is given by \( n^0 \)-exchange, depicted in Fig. 2. The blobs need modeling and the propagator in the ENJL model also has corrections to the 1/(\( p^2 - m^2_{\text{pole}} \)). The pointlike vertex has a logarithmic divergence which is uniquely predicted [24, 25]. The VMD form-factor in the \( n^0 \gamma \gamma^* \) form-factor, the blobs, were modeled in [13] with a variety of form-factors and as a function of the cut-off \( \Lambda \) (corrected for the overall

Two more comments are needed. The above numbers are for the \(\pi^0\). One needs to take into account the \(\eta\) and \(\eta'\) exchange as well. The latter is enhanced due to the charge combinations in the \(\eta'\gamma\gamma\) vertex. In large \(N_c\) models like the ENJL model, the pseudoscalar spectrum is not like QCD, one has a \(\pi^0\), a \(\pi^\pm,\pi^0\) (\(\bar{u}u + \bar{d}d\) quark content) and a \(\pi_\rho\) (\(\bar{s}s\)). The \(\rho\) has the same mass as the \(\pi^0\) and due to the quark charges it contributes 25/9 times the \(\pi^0\) contribution. Lattice QCD calculations with only connected diagrams included will have the \(\pi^0\) contribution as well so there will be an unphysical enhancement compared to the QCD result for the pseudoscalar exchange part. This is discussed in more detail in [15]. In [13] we used pointlike-VMD to estimate the ratio of \(\pi^0,\eta,\eta'\) contributions as 5.58, 1.38, 1.04. Models that include large \(N_c\)-breaking effects and fit the mixings to data typically end up with very similar numbers. The total pseudoscalar exchange contribution I thus estimate to be

\[
a_{\rho^0} = (8-10) \times 10^{-10}
\]  

(3)

An example of a specific calculation is the AdS/QCD result of \(a_{\rho^0} = 1.07 \times 10^{-10}\) [33] which also includes excited pseudoscalars.

The other comment is that the short-distance behaviour of the four-point function is known in several limits. In particular when \(P_1^2 \approx P_2^2 \gg Q^2\) the four point function is related to the axial-vector-vector-vector three-point function [34]. This three point function has a number of exact properties in QCD and we thus know how it behaves. The above models for \(\pi^0\)-exchange do not exhibit this behaviour. It can be implemented via making one of the blobs in Fig. 2 pointlike [34] and one then obtains \(7.7 \times 10^{-10}\) for the \(\pi^0\)-exchange contribution. Plots how this affects the contribution of different Momentum regions are in [8]. The above behaviour of the four-point function must be obeyed in a full calculation, however whether one implements it in \(\pi^0\)-exchange is a choice. Models incorporating a short-distance quark-loop contribution have the short-distance part of this included [8, 26]. One can see this when comparing quark-loop plus pseudo-scalar exchange of [13] with pseudo-scalar exchange of [34].

4 \(\pi\)-loop

The \(\pi\)-loop contribution to the four-point function is depicted in Fig. 3. The leftmost diagram is the naive one, the other two are required by gauge-invariance. In more general models also a diagram with three photons in one vertex and one with all four in the same vertex might be needed. These have been included in the calculations mentioned below when needed.

The simplest model is a point-like pion or scalar QED (sQED). This gives a contribution of about \(-4 \times 10^{-10}\).

The single photon vertex is in all determinations used as including the pion form-factor. For this one can use either the VMD expression or a more model/experimental inspired version. For the \(\pi\gamma\gamma\gamma\) vertex there were originally two main approaches used, full VMD (BPP) and the hidden local symmetry model with vector mesons (HLS). The former is essentially using sQED and putting a VMD-like form-factor in all the photon legs. This was proven to be a consistent procedure in [13]. We obtained there a result of \(-1.9 \times 10^{-10}\) using an ENJL inspired pion form-factor. Using a simple VMD typically gives about \(-1.6 \times 10^{-10}\). This version is exactly what is called the model-independent part of the two-pion contribution in [4, 32, 35]. The reason for the lower number compared to the point-like pion loop is obvious in Fig. 4 where we show \(a_{\rho^0}^{\pi^0}\) of (2) as a function of \(P_1 = P_2 = P\) and \(Q\).

HKS [19, 20] used a different approach. Due to the then existing arguments against full VMD they used the hidden local symmetry model with only vector mesons (HLS) and obtained \(-0.45 \times 10^{-10}\). The difference between this and the previous numbers was the reason for the large error quoted on the pion-loop. This difference was rather
From this we conclude that a number in the range very similar numbers as full VMD. This is shown in Fig. 6

different 

\(\pi\) does not give a finite prediction for the

VMD, notice the different momentum scales compared to the earlier figures. As expected, the charge radius effect is included in the VMD result since the latter gives a good description of the pion form-factor. Including the effect of the polarizability can be done in ChPT by using experimentally determined values for \(L_0\) and \(L_{10}\). The latter can be determined from \(\pi^+ \rightarrow e\nu\) or the hadronic vector two-point functions. Both are in good agreement and lead to a prediction of the pion polarizability confirmed by the COMPASS experiment [39]. The effect of including this in ChPT on \(a_{\mu}^{LLQ}\) is shown in Fig. 8 [15, 36, 37]. An increase of 10-15\% over the VMD estimate can be seen.

ChPT at lowest order or \(p^4\) for \(a_{\mu}\) is just the pointlike pion loop or sQED. At NLO pion exchange with pointlike vertices and the pion loop calculated at NLO in ChPT are

More recently, it was pointed out that the effect of pion polarizability was neglected in these calculations and a first estimate of this effect given using the Euler-Heisenberg four photon effective vertex produced by pions [38] within Chiral Perturbation Theory. This approximation is only valid below the pion mass. In order to check the size of the pion radius effect and the polarizability we have implemented the low energy part of the four-point function and computed \(a_{\mu}^{LLQ}\) for these cases. Partial results are in [36, 37] and the full results in [15]. The effect of the charge radius is shown in Fig. 7 compared to the

VMD, notice the different momentum scales compared to the earlier figures. As expected, the charge radius effect is included in the VMD result since the latter gives a good description of the pion form-factor. Including the effect of the polarizability can be done in ChPT by using experimentally determined values for \(L_0\) and \(L_{10}\). The latter can be determined from \(\pi^+ \rightarrow e\nu\) or the hadronic vector two-point functions. Both are in good agreement and lead to a prediction of the pion polarizability confirmed by the COMPASS experiment [39]. The effect of including this in ChPT on \(a_{\mu}^{LLQ}\) is shown in Fig. 8 [15, 36, 37]. An increase of 10-15\% over the VMD estimate can be seen.

ChPT at lowest order or \(p^4\) for \(a_{\mu}\) is just the pointlike pion loop or sQED. At NLO pion exchange with pointlike vertices and the pion loop calculated at NLO in ChPT are

puzzling, one reason could be that the HLS model does not have the correct QCD short distance constraint when looking at the two-photon vertex with the same and large virtuality for both photons, the full VMD model has the correct behaviour. This version of the HLS model also does not give a finite prediction for the \(\pi^+\pi^0\) mass difference. The reason for the large numerical difference is indeed the short distance behaviour. The low momentum behaviour is very close but the negative contribution above 1 GeV, clearly visible in Fig. 5, is the main reason for the difference [15, 36]. A comparison as a function of the cut-off can be found in [37]. In fact, using the HLS with an unphysical value of the parameter \(a\) = 1, which then satisfies the abovementioned short-distance constraint gives very similar numbers as full VMD. This is shown in Fig. 6. From this we conclude that a number in the range \(-(1.5\ldots1.9)\times10^{-10}\) is more appropriate with an error of half to 1/3 that.

Figure 4. The momentum dependence of the pion loop contribution. Plotted is \(a_{\mu}^{LLQ}\) of (2) as a function of \(P_1 = P_2\) and \(Q\). Top surface: sQED, bottom surface: full VMD.

Figure 7. \(-a_{\mu}^{LLQ}\) of (2) as a function of \(P_1 = P_2\) and \(Q\). Top surface: full VMD, bottom surface: ChPT with \(L_0 = -L_{10}\) so the charge radius is included but no polarizability.

Figure 8. \(-a_{\mu}^{LLQ}\) of (2) as a function of \(P_1 = P_2\) and \(Q\). Bottom surface: full VMD, top surface: ChPT with \(L_0 = -L_{10}\) so the charge radius and the polarizability are included.
needed. Both gives divergent contributions to $a_\mu$, so pure ChPT is of little use in predicting $a_\mu$. If we want to see the full effect of the polarizability we need to include a model that can be extended all the way, or at least to a cut-off of about 1 GeV. For the approach of [38] this was done in [40] by including a propagator description of $a_1$ and choosing it such that the full contribution of the pion-loop to $a_\mu$ is finite. They obtained a range of $-(1.1-7.1) \times 10^{-10}$ for the pion-loop contribution. I find this range much too broad. One reason is that the range of polarizabilities used in [40] is simply not compatible with ChPT. The pion polarizability is an observable where ChPT should work and indeed the convergence is excellent. The ChPT prediction has also recently been confirmed by experiment. Our work discussed below indicates that $-(2.0 \pm 0.5) \times 10^{-10}$ is a more appropriate range for the pion-loop contribution.

The work described below is published in [15]. Preliminary results have been reported at several conferences, see e.g. [41, 42]. The polarizability comes from $L_9 + L_{10}$ in ChPT. Using [43], we notice that the polarizability is produced by $a_1$-exchange depicted in Fig. 9. This is depicted pictorially in the left diagram of Fig. 9. However, once such an exchange is there, diagrams like the right one in Fig. 9 lead to effective $\pi \pi \gamma \gamma$ vertices and are required by electromagnetic gauge invariance. This was done in [40] via the propagator modification. We deal with them via effective Lagrangians incorporating vector and axial-vector mesons.

If one looks at Fig. 9 one could raise the question “Is including a π-loop but no $a_1$-loop consistent?” The answer is yes with the following argument. We can first look at a tree level Lagrangian including pions $\rho$ and $\omega$. We then integrate out the $\rho$ and $a_1$ and calculate the one-loop pion diagrams with the resulting Lagrangian. In the diagrams of the original Lagrangian this corresponds to only including loops with at least one pion propagator present. Numerical results for cases including full $a_1$ loops are presented as well below [15]. As a technicality, we use anti-symmetric vector fields for the vector and axial-vector mesons. This avoids complications due to $\pi$-$a_1$ mixing. We add vector $V_{\mu}$ and axial-vector $A_{\mu \nu}$ nonet fields. The kinetic terms are given by [43]

$$-\frac{1}{2} \left( \nabla^4 V_{\mu} \nabla^\nu V^{\mu \nu} - \frac{M_I^2}{2} V_{\mu \nu} V^{\mu \nu} \right) + V \leftrightarrow A. \quad (4)$$

First we add the terms that contribute to the $L_i$ [43]

$$\frac{F_V}{\sqrt{2}} \left( j_{\mu \nu}^{\pi \rho} V^{\mu \nu} \right) + i \frac{G_V}{\sqrt{2}} \left( A^{\mu \nu \rho} u_\rho \right) + \frac{F_A}{\sqrt{2}} \left( f_{\mu \nu} A^{\mu \nu} \right) \quad (5)$$

with $L_9 = \frac{F_G G_V}{2 M_I^2}$, $L_{10} = -\frac{F_2}{4 M_V^2} + \frac{F_1^2}{4 M_I^2}$. The Weinberg sum rules imply in the chiral limit $F_0^\mu = F_1^\mu + F_2^\mu$. $F_1^\mu = F_I^2 $ and requiring VMD behaviour for the pion form-factor $F_V G_V = F_0^\mu$.

First, look at the model with only $\pi$ and $\rho$. The one-loop contributions to $\Pi^{\rho\rho\rho}$ are not finite. They were also not finite for the HLS model of HKS, but the relevant $\partial \Pi^{\rho\rho\rho}/\partial q_3$ was. However, in the present model it is only finite for $G_V = F_V/2$ and then the result for $a_\mu$ is identical to the HLS model. The same comments as made for the HLS model thus also apply.

Next we do add the $a_1$ and require $F_2 \neq 0$. After a lot of work we find that $\partial \Pi^{\rho\rho\rho}/\partial q_3 = 0$ is finite only for $G_V = F_V = 0$ and $F_A^2 = -2 F_2^2 \rho$, or, if including a full $a_1$-loop $F_A^2 = -2 F_2^2 \rho$. These solutions are clearly unphysical. We then add all $\rho \mu \pi$ vertices given by

$$A_1 \left( \left[ V^{\rho \mu \nu} A_\nu \right] \right) + A_2 \left( \left[ V^{\rho \mu \nu} A_\nu \right] h_\rho \right) + A_3 \left( \left[ V^{\rho \mu \nu} A_\nu \right] u_\rho \right) + A_4 \left( \left[ V^{\rho \mu \nu} A_\nu \right] f_\rho \right) + A_5 \left( V^{\rho \mu \nu} A_\nu A_\rho \right). \quad (6)$$

These are not all independent due to the constraints on $V_{\mu \nu}$ and $A_{\mu \nu}$ [44], there are three relations. After a lot of work [15] we found that no solutions with $\partial \Pi^{\rho\rho\rho}/\partial q_3 = 0$ exists except those already obtained without $A_1$ terms. The same conclusions holds if we look at the combination that shows up in the integral over $P_1^2, P_2^2, Q^2$. We thus find no reasonable model that has a finite prediction for $a_\mu$ for the pion-loop including $a_1$. If we choose the parameters as fixed by the Weinberg sum rules and the VMD behaviour of the pion-form factor we obtain $a_\mu^{LLQ}$ as shown in Fig. 10. Adding a full $a_1$-loop changes the plot only marginally. As long as we require the correct polarizability and a VMD-like form-factor behaviour, the plots look quite similar for all cases below 1 GeV. The integrated value up to $\Lambda$ for a number of cases is how in Fig. 11. We see that all models end up with a value of $a_\mu = -(2.0 \pm 0.5) \times 10^{-10}$ when integrated up-to a cut-off of order 1-2 GeV. We conclude that that is a reasonable estimate for the pion-loop contribution. The main missing part is the $\pi-\pi$ rescattering.
The dispersive approach has numbers that are compatible with the above and the inclusion of scalar exchange, $a_{\pi}\text{loop}^\Lambda=0.3\text{ GeV}$. The lines indicate the surface.

![Figure 11. $-a_{\mu}$ using a variety of models for the pion loop as a function of $\Lambda$, the cut-off on the photon momenta. Figure from [15].](image)

5 Quark-loop

The pure quark-loop contribution with a constant mass is known analytically. One of the surprises is that it converges rather slowly. A significant portion is from high momentum regions. With a constituent quark mass of 300 MeV and a cut-off of 1(2) GeV 50(25)% of the full contribution is still missing. A more visual illustration of this is the plot of $a_{\mu}^{\pi\pi}$ defined in (2) of this contribution. The contribution is plotted in Fig. 12 as a function of $P_1$ and $Q$ for several ratios of $P_2/P_1$. The volume under the curve is proportional to $a_{\mu}$. The contribution peaks for $P_1\approx P_2\approx Q$ and around 1 GeV. In [13] we used the ENJL up to a cut-off $\Lambda$ and added a short-distance quark-loop where we used the quark-mass $M_H=\Lambda$ as a lower cut-off. The estimate used by HKS was a quark-loop damped by VMD factors in the photon legs. The results are given in Tab. 2. Notice especially the stability when we add the ENJL and the short-distance contribution in the region $\Lambda=1-8$ GeV. The conclusion is that the quark-loop is about $2\times 10^{-10}$. In the ENJL model the quark-loop and scalar exchange are needed together to have correct chiral symmetry. The sum of both is very similar to the quark-loop estimate of HKS.

There are a number of estimates of the quark-loop that lead to much larger numbers. These have all in common that there is a momentum region with a fairly small (constituent) quark mass that is not shielded by a VMD-like mechanism. The most prominent example of this is the DSE estimate of [47] $10.7(0.2)\times 10^{-10}$. The present status of this calculation is given in [16]. It not yet a full calculation but includes an estimate of some of the missing parts. This DSE model describes a lot of low-energy phenomenology in a way very similar to the ENJL model. I am quite puzzled by the difference in results.

Similar size numbers are obtained in models with a low constituent quark mass where no VMD-like dynamical effects are included. Examples are the nonlocal chiral quark model [48] with $11.0(0.9)\times 10^{-10}$ and a number of estimates within the chiral quark model $(7.6-8.9)\times 10^{-10}$ [29], $(11.8-14.8)\times 10^{-10}$ [49] and $(7.6-12.5)\times 10^{-10}$ [50]. The interpretation varies from an estimate to the full HLS or just a part that needs to be added to other contributions.

Table 2. The quark-loop contribution with VMD damping, the ENJL model and with a heavy quark mass as cut-off. The numbers are $a_{\mu}\times 10^{10}$.

6 Scalar exchange

The estimate of the scalar exchange contribution in the ENJL model is $-0.7\times 10^{-10}$. Similar size estimates have been obtained when exchanging a sigma-like particle. It should be pointed out that the scalar in the ENJL model has a phenomenology similar to the sigma but is quite a different underlying object.

A problem here is to distinguish scalar exchange from two-pion or pion-loop contributions. This is one of the areas where the method of [4, 32] as used in [45, 46] allowed for major progress.

7 $a_1$-exchange

The exchange of axial vectors in the ENJL model was estimated in [13] to be about $0.6\times 10^{-10}$, but due to the high mass involved, even with a cut-off of 2 GeV only half the
contribution was there. The ENJL part also includes some pseudo-scalar meson exchange due to the structure of the calculation.

Axial-vector meson exchange in a more phenomenological way was done using two multiplets in [34] who obtained $2.2 \times 10^{-10}$. It was later found that when correct antisymmetrization is included, this becomes smaller by a significant factor and is again in the ballpark of the ENJL result. This was noticed by F. Jegerlehner. He obtains about $(0.76 \pm 0.27) \times 10^{-10}$ for the axial-vector exchange [51, 52]. The evaluation of [53] is also in reasonable agreement with the ENJL estimate.

8 Conclusions

The present number for the HLS contribution to the muon anomaly, $a_\mu = (g_\mu - 2)/2$, is $(11 \pm 4)$ or $(10.5 \pm 2.6) \times 10^{-10}$ [8–10] depending somewhat on which error estimates and which contributions are taken into account. In this talk I have given an overview of a number of model estimates with the emphasis on my old work [12–14] as well as a number of newer developments. For the latter I have spent quite some time on our reevaluation of the pion loop contribution [15, 36, 37, 41, 42], as well as given a number of arguments why the HLS number of [19, 20] should be considered obsolete. The conclusion is that the pion loop contributes with $-(2.0 \pm 0.5) \times 10^{-10}$.

One of the remaining problems in the model approach is that the class of models with an “unshielded” quark-loop at relatively low-energies for the photons tend to obtain larger numbers. Whether this is a real phenomenon or not is a question which needs to be settled. My own opinion is that I see no counterpart of it in $\gamma\gamma \rightarrow$ hadrons at low to intermediate energies beyond the already included single meson and two-pion exchanges.

For contributions of different mechanisms, progress can be expected both from the dispersive approaches mentioned and experiment restricting the couplings of off-shell or virtual photons to meson that go into the modeling. Alternatively, a full new model calculation that includes phenomenology beyond what the ENJL does, is very desirable as well as more work on the short-distance aspects.

Acknowledgements

I thank the organizers for the very nice atmosphere and the many opportunities to discuss the issues regarding HLS. This work is supported in part by the Swedish Research Council grants 621-2013-4287, 2015-04089 and 2016-05996 and by the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement No 668679).
