Status of the Mu2e experiment

S. Giovannella\textsuperscript{1, a} on behalf of the Mu2e Collaboration
\textsuperscript{1} Laboratori Nazionali di Frascati dell’INFN, via Enrico Fermi 40, 00044 Frascati, Italy

Abstract. The Mu2e experiment at Fermilab searches for the charged-lepton flavor violating neutrino-less conversion of a negative muon into an electron in the field of an aluminum nucleus. The dynamics of such a process is well modelled by a two-body decay, resulting in a mono-energetic electron with an energy slightly below the muon rest mass. If no events are observed, in three years of running Mu2e will improve the current limit by four orders of magnitude. Such a charged lepton flavor-violating reaction probes new physics at a scale inaccessible with direct searches at either present or planned high energy colliders. The experiment both complements and extends the current search for muon decay to electron-photon at MEG and searches for new physics at the LHC. This paper focuses on the physics motivation, the design and the status of the experiment.

1 Introduction

Differently from their hadronic counterpart, charged lepton flavor transitions are not allowed in the Standard Model (SM) with massless neutrinos. Even including neutrino mass, charged lepton flavor violation (CLFV) processes are extremely suppressed in the SM, with rates smaller than $10^{-50}$ \cite{1}. On the other hand, a broad variety of new physics Beyond the Standard Model (SU5, Leptoquarks, GUT, ...), predicts significantly larger rates, within the reach of next generation of CLFV experiments \cite{2}. Because of the negligible background, any CLFV experimental detection would be a clear indication of new physics.

Searches in muon channels are of particular interest because of their high rates and the possibility of carrying out clean measurements free of hadronic corrections in the calculation. Comparison of current limit and expectations from next generation experiment with other channels are reported in Fig. 1. The experimental search for CLFV with muons ($\mu \rightarrow e\gamma$, $\mu \rightarrow 3e$, and $\mu N \rightarrow eN$, i.e. the muon to electron conversion in the field of a nucleus) is progressing extremely fast in the last decades. Current best limits are $BR(\mu \rightarrow e\gamma) < 4.2 \times 10^{-13}$ at 90 \% C.L. (MEG \cite{3}) and $R_{\mu e} < 7 \times 10^{-13}$ (SINDRUM-II \cite{4}). A solid international program exists with the MEG upgrade \cite{5} underway, a proposed $\mu \rightarrow 3e$ experiment at PSI (Mu3e \cite{6}) and with the approved programs on the muon to electron conversion at FNAL (Mu2e) \cite{7} and J-PARC (COMET/DeeMe) \cite{8, 9}.

2 The Mu2e Experiment

The goal of the Mu2e experiment is to improve by four orders of magnitude the best previous measurement and reach a single event sensitivity of $3 \times 10^{-17}$ on $R_{\mu e}$, the rate of neutrino-less conversion of a muon into an electron in the field of a nucleus with respect to the dominant muon capture process. The experimental technique consists of a high intensity beam of low momentum muons stopped in an aluminum target and trapped in orbit around the nucleus, with a lifetime in the bound state of $\tau_{\mu} = 864 \text{ ns}$. The distinctive signature of the conversion electron (CE) line has to be distinguished, with a high momentum resolution. Figure 1. Current best limits on CLFV searches and expectations from next generation experiments.

\caption{Current best limits on CLFV searches and expectations from next generation experiments.}
\end{table}
The Mu2e experiment is designed to have a discovery sensitivity of 5 standard deviations or better. Apart from the DIO contribution, an additional background source comes from the radiative pion capture (RPC), \( \pi + N \rightarrow \gamma + N' \). Here, the electron positron pair, produced either by internal or external conversion, becomes a source of fake CE candidates when the e\(^-\) momentum is in the selection window.

In order to reach the required sensitivity, the experiment has to collect \( 10^{18} \) stopped muons with a number of background events less than 0.5. These considerations have driven the design strategy of Mu2e, based on four key elements:

1. A high intensity muon beam
   The goal is to increase the muon intensity by \( 10^4 \) w.r.t. previous experiments to reach \( 10^{11} \) muons/s on target. This is obtained combining a high rate particle production and a curved solenoidal system to create a transport channel that selects both charge and momentum.

2. A pulsed beam structure
   Mu2e has selected an aluminium target where the muon lifetime in the bound system (\( \tau_\mu = 864 \) ns) well matches the bunch period of the Fermilab accelerator (micro-bunch of 1694 ns period). The trick is to wait for the prompt backgrounds to decay and start the data acquisition \( \sim 700 \) ns after the bunch arrival time (Fig. 4).

3. A proton extinction better than \( 10^{-10} \)
   The number of protons traveling in the beam in the out of time window has to be reduced to the indicated level with respect to the in time protons.

4. A redundant high-precision detector
   This is needed to analyse the products from muon interaction on target to separate CE and DIO spectra and make the contribution from additional background sources negligible.

The layout of the Mu2e experiment is shown in Fig. 5. A series of superconducting solenoids forms a graded magnetic system composed of a Production Solenoid, PS, a Transport Solenoid, TS, and a Detector Solenoid, DS. The PS contains a tungsten target that is struck by an 8 GeV pulsed proton beam. A gradient field in the PS (from 2.5 to 4.6 Tesla) acts as a magnetic lens to focus the produced low energy particles (pions, muons and a small number of antiprotons) into the transport channel. The S-shaped Transport Solenoid efficiently transfers low energy, negatively charged particles to the end of the beamline while allowing a large fraction of pions to decay into muons. Positive and negatively charged particles drift in opposite directions while traveling through the curved solenoidal field, and a mid-section collimator removes nearly all the positively charged particles. The DS uses a graded field from 2 to 1 Tesla in the upstream region where the stopping target resides to increase acceptance for CE events. An uniform magnetic field of 1 Tesla occupies the region of the tracker and calorimeter systems. Approximately 50% of the muon beam, whose momentum is \( \sim 50 \) MeV, is stopped by the target; the surviving beam stops on the beam dump at the end of the cryostat. A muon stopping rate of 10 GHz allows the experiment to reach the final goal of \( 10^{19} \) stopped muons on target in three years of running. Muons that stop in the aluminium target are captured in an atomic excited state and promptly cascade to the 1S ground state with 39% decaying in orbit and the remaining 61% captured by the nucleus. Low energy photons, neutrons and protons are emitted in the nuclear capture process. These make up an irreducible
source of accidental activity that is the origin of a large neutron fluence on the detection systems. Together with the flash of particles accompanying the beam, the capture process produces the bulk of the ionizing dose observed in the detector system and its electronics.

The Mu2e tracker is the primary device to measure the momentum of the electron and separate it from background. The crystal calorimeter plays a crucial role in providing particle identification capabilities and a fast online trigger filter, while aiding the track reconstruction capabilities. An external veto for cosmic rays surrounds the solenoid. An extinction monitor detects scattered protons from the production target to evaluate the fraction of out-of-time beam and a stopping target monitor measures the rate and the number of negative muons that stop in the target.

3 Tracker

The Mu2e tracker system [10] has been designed to maximizing acceptance for conversion electrons (CE), minimizing the contamination from the muon Decay-In-Orbit (DIO) background. Nuclear modifications push the DIO spectrum towards the CE signal; energy loss and detector resolution produce overlap of the two processes. The selected design is based on nearly 20,000 low mass straw drift tubes of 5 mm in diameter, with 15 µm Mylar wall and 25 µm sense wire. Straws are oriented transversally to the solenoid axis and arranged in 18 stations for a total length of 3.2 metres. A central hole, 38 cm in diameter, makes the device blind to low momentum background particles. (Fig. 6).

Tracker performance has been studied by Monte Carlo using Mu2e full simulation. Results are reported in Fig. 7. The core momentum resolution of 115 keV/c, with a 3% high tail slope of 179 keV/c, is well within physics requirements and stable when increasing accidental hit rate. The total track efficiency of ~ 9% is fully dominated by geometric acceptance.

An eight channel tracker prototype has been built and tested with cosmic rays. In Fig. 8 the extracted position resolution is compared with Monte Carlo expectations. The shift observed in the transverse resolution is due to the $T_0$ calibration differences. The transverse resolution extracted with a Gaussian fit is $(0.133 \pm 0.022)$ mm for data and $(0.102 \pm 0.001)$ mm for Monte Carlo simulation. The values extracted for the longitudinal resolution are $\sigma_{\text{data}} = (42 \pm 1)$ mm and $\sigma_{\text{MC}} = (43 \pm 1)$ mm.

A first pre-production prototype with final design was recently built and is being tested. A vertical slice test on fully instrumented panels with the entire FEE chain will follow.
4 Calorimeter

The Mu2e calorimeter [11] has to provide confirmation for CE signal events, a powerful e/µ separation - with a muon rejection factor of ~ 200, a standalone trigger and seeding for track reconstruction. An energy resolution of O(5%) and a time resolution < 500 ps for 100 MeV electrons are sufficient to fulfill these requirements. The calorimeter design consists of two disks made by 674 undoped CsI scintillating crystals with (34 × 34 × 200) mm³ dimension (Fig. 9). Each crystal is read-out by two custom array large area (2 × 3 of 6 × 6 mm² cells) UV-extended Silicon PhotoMultipliers (SiPMs). The crystals will receive an ionizing dose of 90 krad and a fluence of 3 × 10¹² n/cm² in three years running. The photosensors, being shielded by the crystals, will get a three times smaller dose.

A small calorimeter prototype, a 3 × 3 array of CsI crystals coupled to a single multi-pixel photon counter, has been tested at the Frascati Beam Test Facility with electron beams of 80–120 MeV [12]. A time resolution of 100 ps and an energy resolution of 6.5% has been obtained for 100 MeV particles (Figs. 10, 11). For the latter, a significant leakage contribution is present, confirmed by simulation.

Pre-production components both for crystals and SiPMs have been received from different vendors. They have been characterized and irradiation test have been car-
ment prototype, with 51 crystals and 102 SiPMs and front end boards, testing integration and assembly procedures.

5 Cosmic Ray Veto

The major background source in Mu2e is due to cosmic ray muons that produce fake CE candidates when interacting with the detector materials. These events occur at
a rate of approximately one/day. In order to reduce their contributions in the experiment lifetime, the external area of the DS, and a part of the TS, are covered by a Cosmic Ray Veto (CRV) system \([7]\), shown in Fig. 12. The requirement for the CRV system is to obtain a veto effi-
ciency of at least 99.99\% for cosmic ray tracks while with-
standing an intense radiation environment. Comprised of
four staggered layers of scintillation slabs (Fig. 13), the
CRV counters are read out with two embedded wavelength shifting fibers, each one in optical contact with a (2 \times 2) mm\(^2\) Hamamatsu SiPM. Test beams on full size prototype
have been carried out demonstrating that the needed light yield can be reached \([13]\): the measured number of photo-
electrons obtained at 1 meter from the readout end provides
a safety factor of \(\sim 40\%\) with respect to the requirement.
Irradiation of SiPMs with neutrons have also been done to understand the maximum level of fluence acceptable for
operations.

6 Expectations with full simulation

At 100 MeV, the momentum resolution is dominated by
the fluctuations in the energy loss in the stopping target and bremsstrahlung in the tracker, with the trajectory altered by multiple scattering. The resolution for CE tracks
is well-parametrised by a Crystal Ball function with a neg-
ate bremsstrahlung tail, a gaussian core of 116 keV and

The Mu2e experiment has, as of this writing, successfully procured all superconducting cables, completed civil construction and obtained CD-3 (Critical Decision 3) from DOE. CD-3 grants permission to start the construction for the accelerator, the magnetic system, the muon beam line and all the detector components. The heart of the Mu2e apparatus is provided by the superconducting magnetic system whose design, fabrication, assembly and commissioning drives the schedule of the experiment. The status of the magnet as well as the construction and testing of the superconducting cables is satisfactory. An international bid for the DS and PS has been concluded and the construction phase for the large magnets is started at General Atomics, San Diego, USA. For the TS, after the construction of one module prototype by ASG Superconducting, in collaboration with the INFN group of Genova, the contract has been awarded to ASG. Construction of the 52 coils has been awarded to ASG. Construction of the 52 coils is progressing well, with the first 32 already being completed. The first TS module, assembled with two coils, is being delivered and then fully qualified at the HAB test facility in Fermilab. All systems are concluding the prototyping phase. Production of final components is starting, and it will move to full regime by the end of 2017. The schedule foresees a completion of the installation of detectors and commissioning with cosmic rays at the end of 2020.

8 Conclusions

The Mu2e experiment will exploit the world’s highest intensity muon beams of the Fermilab Muon Campus to search for CLFV, improving current sensitivity by a factor $10^3$ and with a discovery capability over a wide range of New Physics models. A low mass straw tube tracker, a pure CsI crystal calorimeter with SiPM readout and a high efficiency cosmic ray veto have been selected to satisfy the demanding requirements. The construction of the detectors is beginning at the moment of writing. Detector installation is foreseen in 2020, followed by Mu2e commissioning and data taking.
