Abstract. The phase and structural states of nanocrystalline Fe-based films alloyed with Zr and N, which were prepared by reactive magnetron sputtering under different conditions, magnetic-structure parameters of the films and their static and high-frequency magnetic properties have been studied. The interrelation of static magnetic properties and magnetic-structure parameters with the value of real effective magnetic permeability \( \mu' \) and frequency range, for which the value is unchanged, has been studied.

1 Introduction

The designing of miniature high-frequency induction electronic devices used for radiocommunication, data storage, etc., which operate in the high-frequency (up to gigahertz range) ac magnetic fields, is the today’s trend of the modern microelectronics. Film amorphous and nanocrystalline soft magnetic materials intended for these devices should exhibit the high saturation resonance (nFMR) fields, and high frequency of natural ferromagnetic magnetic permeability this case, the films should be characterized by high magnetization these devices should exhibit the high saturation magnetic permeability of the modern microelectronics. Film amorphous and nanocrystalline states, in particular, by magnetron sputtering, and, on the other hand, to the prospect to prepare such films with unique static and HF soft-magnetic properties [7-11].

The aim of the present work is to study the correlation between static magnetic properties, magnetic-structure parameters and a value of real effective magnetic permeability \( \mu' \) in frequency range, in which \( \mu' \) is unchanged (nFMR), of Fe-Zr-N films prepared by magnetron sputtering under different conditions.

2 Experimental

The Fe-Zr-N films were prepared by magnetron sputtering of the Fe-2.4 wt. % Zr target being a Fe disc with evenly distributed Zr chips. In the magnetron chamber under exposure to plasma flame there occurred surface melting of Fe and Zr forming different alloys of Fe-Zr system in the erosion zone. Before each sputtering, the target was heated above Curie temperature using plasma at which sputtering process was held. Deposition took place in gas atmosphere of Ar + 5 [%] N2 or Ar + 15 [%] N2 under total pressure of pAr+N2 0.3 Pa. As substrates, we used glass plates with the thickness of \( d_s = 0.4 \) mm. The thickness of prepared films was estimated by glow-discharge optical emission spectroscopy [12], which was performed on a Horiba Jobin Yvon Profiler-2 instrument; the thickness was \( d_f = 1.2 \pm 0.2 \) \( \mu \)m. 

The Fe-Zr-N films were prepared by magnetron sputtering of the Fe-2.4 wt. % Zr target being a Fe disc with evenly distributed Zr chips. In the magnetron chamber under exposure to plasma flame there occurred surface melting of Fe and Zr forming different alloys of Fe-Zr system in the erosion zone. Before each sputtering, the target was heated above Curie temperature using plasma at which sputtering process was held. Deposition took place in gas atmosphere of Ar + 5 [%] N2 or Ar + 15 [%] N2 under total pressure of pAr+N2 0.3 Pa. As substrates, we used glass plates with the thickness of \( d_s = 0.4 \) mm. The thickness of prepared films was estimated by glow-discharge optical emission spectroscopy [12], which was performed on a Horiba Jobin Yvon Profiler-2 instrument; the thickness was \( d_f = 1.2 \pm 0.2 \) \( \mu \)m.

The phase composition and fine structure (the coherent domain size corresponding to the grain size 2\( R \), and the microstrain \( \varepsilon \) at grain scale) were studied by X-ray diffraction (XRD) analysis using a Rigaku Ultima IV diffractometer equipped with a graphite monochromator, CuK\( \alpha \) radiation, Bragg-Brentano geometry, and original
software for full-profile Rietveld analysis [13]. Magnetic hysteresis loops were measured in magnetic fields up to 16 kOe using a LakeShore 7407 vibrating-sample magnetometer. The error of measurement of saturation induction, which is related to the difference in the shape and dimensions of Ni standard sample (3 mm in diameter) and used samples, did not exceed ~10%. Magnetic structure parameters were estimated by correlation magnetometry [6].

The microwave permeability of the films is measured by the stripline technique [14] using square-shaped plate samples 23 mm in the plate dimension. The technique involves calibration measurements of two samples with a known permeability to eliminate the measurement uncertainty appeared because of intrinsic non-uniformities in the measuring setup. The measurements are made in the frequency range of 0.1 to 2 GHz in two perpendicular directions (x and y). From the measured effective permeability of the sample, \( \mu_{\text{measured}} \), the intrinsic permeability of the film, \( \mu_{\text{intrinsic}} \), is found by equation \( \mu_{\text{measured}} = 1 + \rho(\mu_{\text{intrinsic}} - 1) \), where \( \rho = d/d_s \leq 0.003 \) is the content of the ferromagnetic constituent in the sample.

### 3 Results and discussion

#### 3.1 Phase composition and structure

According to XRD data, the films under study are either amorphous (in terms of X-ray diffraction) or nanocrystalline (Fig. 1), depending on the nitrogen content in the magnetron chamber. At the nitrogen content of 5%, the phase composition of prepared film consists of two nitride nanocrystalline phases, such as Fe,N and Fe,N with a grain size of 3–6 nm. As the nitrogen content in the magnetron chamber increases from 5 to 15%, the amorphous structure enriched in Fe is formed in the films (Table 1, Fig. 1a). According to our previous magnetic studies [15], the Fe-Zr-N films with the amorphous structure, which gives a wide reflection in X-ray diffraction patterns, consist of \( \alpha \)-Fe-based ferromagnetic grains less than 2 nm in size.

#### 3.2 Static magnetic properties and magnetic structure

As is known, the origin of static coercivity and magnetic permeability in nanocrystalline ferromagnets is explained by a random magnetic anisotropy model [5,6]. According the model the local effective magnetic anisotropy at the grain scale \( D(1/2)H_a \) is suppressed when the grain size 2\( R_c \) is less than the exchange interaction length \( R_L \). In this case, uniform magnetization domains 2\( R_L \) (the stochastic domains) determined by exchange interaction are formed in the nanocrystalline ferromagnet and its magnetic hysteresis in low magnetic fields is determined by the magnetic anisotropy field at the stochastic domain scale \( D(1/2)H_a \). Note, that several stochastic domain with different \( D(1/2)H_a \) magnitude can be formed in the nanocrystalline ferromagnet. Here, we report results of determination of \( D(1/2)H_a \) and \( D(1/2)H_a \) magnitudes and static magnetic properties of studied films.

![Fig. 1. XRD patterns of studied films deposited at the nitrogen content in the magnetron chamber of 15 and 5% \( N_2 \).](image)

The shapes of hysteresis loops (Fig. 2) allow us to find the simultaneous presence of, at least, two main magnetic anisotropies differing in the value and symmetry. This is indicated by the change in the magnetization curve slope towards the hysteresis loop in the first and third quadrants (Figs. 2a and 2b) and extended hysteresis-free portion of magnetization curve, which corresponds to the magnetization of more than half of film volume (Fig. 2a).

Magnetization curves in high magnetic fields are described by law of approach to magnetic saturation in terms of correlation magnetometry method [16]

\[
M(H) = M_s [1 - (1/2)(D(1/2)H_a)^2/((H^2 + H^{1/2}H_a^{3/2}))].
\]

Using Eq. (1) for the films under study, the saturation magnetization (\( M_s \)), the root-mean-square fluctuation of effective local (at the grain scale 2\( R_c \)) anisotropy field \( D(1/2)H_a \) and exchange field \( (H_a) \) were determined (Table 2). These magnitudes were used to estimate the first (of two anisotropy fields found from the hysteresis loop shape) anisotropy field of stochastic domain (Table 2): \( D(1/2)H_a \geq 1 \approx (D(1/2)H_a)^4/(H_a^2) \). Magnetization dispersion curves 1\( \cdot M(H)/M_s \) plotted on log-log coordinates (insets on Fig. 3) indicate three asymptotes: (I) \( 1 - M(H)/M_s = (1/2)(D(1/2)H_a)^2/H^2 \), (II) \( 1 - M(H)/M_s = (1/2)/(D(1/2)H_a^2)/((H/H)^{3/2}) \) and (III) \( 1 - M(H)/M_s = (1/2)(D(1/2)H_a^2)/H^2 \). The curve connected the second and third asymptotes (IV) is described by Eq. (1). The second root-mean-square fluctuation of effective anisotropy field of stochastic domain \( D(1/2)H_a \) (Table 2) was estimated using asymptote I.
This means that the magnetic hysteresis in the studied films is induced by rotation of stochastic domains with different anisotropy field magnitudes ($D^{1/2}<H_a>^1$ and $D^{1/2}<H_a>^2$, Table 2). In this case, in accordance with theoretical estimations [6], the coercive field of the film should be equal (to a certain approximation) to the anisotropy field of stochastic domains abundantly present in the magnetic structure.

### 3.3 High-frequency magnetic properties

The microwave permeability of the sample deposited in the atmosphere containing 5% N$_2$ is negligible as compared to the measurement error and is not discussed below. The measured microwave permeability of the sample produced at 15% nitrogen content is shown in Fig. 4 for two mutually perpendicular orientation of the film. The magnetic properties of the film are slightly anisotropic in the film plane. The magnetic loss peak observed at frequencies of about 700 MHz is due to the nFMR arising at the effective anisotropy field $H_{eff}$ [8]. For thin films, the relation between nFMR frequency $f_r$ and the effective anisotropy field is given by Kittel’s equation,

$$f_r = \frac{\gamma}{(4\pi M_s H_{eff})^{1/2}}$$

(2)

where $\gamma$ is gyromagnetic ratio. The values of $H_{eff}$ estimated by Eq. (2) from the measured location of the magnetic loss peak are given in Table 3.

It is seen from Tables 2 and 3 that, as the deposition conditions changes (5 and 15 %N$_2$ in magnetron-chamber atmosphere), the $H_{eff}$ and $H_{co}$ magnitudes demonstrate the similar character of variations. This agrees with data of [17], which showed that the $H_{eff}$ magnitude should be proportional to the $H_{co}$ coercive force magnitude. This indicates the fact that the static magnetic structure affects the dynamic magnetic properties. It should be noted that the measured
magnitudes (Table 3) depend on the measurement direction (x and y) and the fact that the unsmoothed magnetization permeability curves (Fig. 4) are likely to indicate the magnetic-structure inhomogeneity.

* Two samples were deposited simultaneously.

The difference between field magnitudes $H_{eff}$, $H_c$ and $D^{1/2}/H_c$, can be explained by decreasing scales at which they are realized, i.e., from macroscopic scale, $H_{eff}$ for whole film, to the maximum fraction with a some magnetic anisotropy close to the $H_c$ and, finally, to microscopic scale, for stochastic domain $D^{1/2}/H_c$. At a frequency of 1 GHz (the wavelength is 30 cm), the magnetic moment of whole film 2.3 cm in length is in resonance oscillations; this determines the $H_{eff}$ magnitude. As it was noted above, the analysis of hysteresis loop shape allows us to assume the presence of, at least, two volumes differing in the magnetic anisotropy of biggest volume. The $D^{1/2}/H_c$ field magnitude is determined from the high-field portion of magnetization curve (Fig. 3) and corresponds to the anisotropy field of stochastic micron-sized domain.

The real effective magnetic permeability $\mu'$ and the frequency range of its “operation” are applied characteristics for high-frequency operation. Table 3 shows the $\mu'$ magnitudes for the studied films and the maximum $f$ frequency for which the $\mu'$ value remains unchanged. Taking into account the measurement accuracy of the film thickness (1.2±0.2 μm), the error of measurement of $\mu'$ is ±17%. The measured $\mu'$ values qualitatively obey the relationship $\mu' = M/H_{eff}$. Note that the Fe-Zr-N films, in particular, Fe$_{89}$Zr$_{10}$N$_{11}$-12 [11,15], have the substantially higher $M_c$ values as compared to those of the films studied in the present work, which reach 1.8-1.9 T. For the films with $M_c = 1.8-1.9$ T, the higher $f$ value and the higher permeability $\mu' = M_c/H_{eff}$ can be expected.

4 Conclusions

Nanocrystalline (with a grain size of 3-6 nm or < 2 nm) soft magnetic FeZrN films prepared by dc magnetron sputtering of the Fe – 2.4 wt% Zr target in the (Ar + N$_2$) atmosphere containing 5 and 15% N$_2$ have been studied. Parameters of magnetic structure ($D^{1/2}/H_{eff}$, $D^{1/2}/H_c$), saturation magnetization $M_s$, (0.5-1.34 T), and magnetic permeability $\mu'$ (80-100) remained unchanged to frequencies of 500 GHz were determined. The dependence of the high-frequency magnetic permeability $\mu'$ and the ac magnetic-field frequency, at which the $\mu'$ magnitude remains unchanged, on the magnetic-structure parameters of the films was considered. It was shown that the static magnetic structure determines the dynamic magnetic properties.

This study was supported in part by the Russian Foundation for Basic Research (projects nos. 18-03-00502 and 18-08-00491).
