### ABSTRACT

Measurements of reactor physics quantities aimed at identifying the reactivity worth of materials, spectral ratios of cross-sections, and reactivity coefficients have ensured reactor physics codes can accurately predict nuclear reactor systems. These measurements were critical in the absence of sufficiently accurate differential data, and underpinned the need for experiments through the 50s, 60s, 70s and 80s. Data from experimental campaigns were routinely incorporated into nuclear data libraries either through changes to general nuclear data libraries, or more commonly in the local libraries generated by a particular institution or consortium interested in accurately predicting a specific nuclear system (e.g. fast reactors) or parameters (e.g. fission gas release, yields). Over the last three decades, the model has changed. In tandem access to computing power and monte carlo codes rose dramatically. The monte carlo codes were well suited to computing k-eff, and owing to the availability of high quality criticality benchmarks and these benchmarks were increasingly used to test the nuclear data. Meanwhile, there was a decline in the production of local libraries as new nuclear systems were not being built, and the existing systems were considered adequately predicted. The cost-to-benefit ratio of validating new libraries relative to their improved prediction capability was less attractive. These trends have continued. It is widely acknowledged that the checking of new nuclear data libraries is highly skewed towards testing against criticality benchmarks, ignoring many of the high quality reactor physics benchmarks during the testing and production of general-purpose nuclear data libraries. However, continued increases in computing power, methodology (GPT), and additional availability reactor physics experiments from sources such as the International Handbook of Evaluated Reactor Physics Experiments should result in better testing of new libraries and ensured applicability to a wide variety of nuclear systems. It often has not. Leveraging the wealth of historical reactor physics measurements represents perhaps the simplest way to improve the quality of nuclear data libraries in the coming decade. Resources at the Nuclear Energy Agency can be utilized to assist in interrogating available identify benchmarks in the reactor physics experiments handbook, and expediting their use in verification and validation. Additionally, high quality experimental campaigns that should be examined in validation will be highlighted to illustrate potential improvements in the verification and validation process.

KEYWORDS: Benchmark, Integral Experiment, Nuclear Data, Validation

## 1. INTRODUCTION

Neutronics predictions underpin the safety, economics, and operation of reactor systems. Reactor physicists are concerned with the applicability and accuracy of their modelling and simulation tools that characterize the steady state and transient behavior of the reactor core. Questions arising such as, will the system be critical (k-eff), how often to fuel, what is the local power peaking, conversion ratio, response of the in-core detection and shutdown system, void reactivity, doppler feedback, isotopic composition of used nuclear fuel, and the potential for medical isotopic production are all central to the design and operation of nuclear systems. Analysts require tools having undergone rigorous verification and validation. The consequences can be large as uncertainties and errors in code predictions can potentially cost billions of dollars [1-3].

Many neutronics tools and methods perform adequately for existing systems. Despite improvements to methods and data, the cost benefit ratio of the validation process is prohibitive to adopting these updates; a case in point is that the nuclear data library of reference for many applications in the UK is JEF2.2, released in 1992. For new tools to be adopted biases and uncertainties need to be determined and documented to at least the standard of the previous versions, requiring significant benchmarking against available experimental data. Furthermore, while outside the scope of this paper, as the codes are coupled to downstream applications such as fuel performance and thermal-hydraulics, the consequences of new biases and uncertainties will not be evident from neutronics testing alone. Mechanisms to quickly provide feedback, in order to communicate and resolve differences, is a key obstacle to overcome.

During the golden age of reactor design (1960's), it was common to build mockups of reactor systems, followed by hundreds of measurements characterizing the system and its feedback coefficients. Neutronics designs became increasingly complex (fast reactors, molten salt systems, thorium systems, accelerator driven systems etc.) and mockups determined the applicability of the simulation tools of-the-day, which at the time were quite uncertain. Validation was big business, and the methods to optimize the process were of the utmost economic importance. Perturbation theory, outlined by Wigner in 1945 [4], was extensively developed, expanded, and applied by Usachev [5] who used these methods to improve experimental design [6]. As perturbation theory methods were increasingly adopted in the 1970s and 80s the methods were widely applied to improve interpolation and extrapolation of experimental results based on similarity of mockups to the reactors being designed, known as representativity. Ushachev wisely recognized the value in sensitivity and uncertainty methods to improve communication between nuclear data evaluators and users [7], which he noted was of increasing importance as discipline specialization increased. During this era, the biases and uncertainties were a mix of analytic approximations and nuclear data, which limited the ability of perturbation theory methods to directly improve nuclear data, especially in thermal systems.

Furthermore, to isolate the impact of nuclear data, credible uncertainties were needed. In the 1970s and prior, there was rarely covariance data in the major evaluated nuclear data libraries. Occasionally covariances were available, but their applicability was limited. Nuclear data evaluators at the time were not universally enthusiastic about adding this information, as the following excerpt from Ref 8. illustrates.

*The discussion of uncertainties within ENDF/B spurred a vigorous debate circa 1974. CSWEG members were heard to say "Uncertainties were too difficult to assign, and virtually impossible to assign over a complete range of data." "Even if assigned, uncertainties would never be used. There simply was not sufficient interest to justify the enormous expense to implement uncertainties in reactor physics codes"*

A consensus on the path forward for nuclear data covariances was far from being reached, although many efforts to generate covariances continued. At the same time, user interest and the need for covariances increased. The landscape changed rapidly in the mid 2000's and many sources of covariance data became available to reactor physics analysts [9-11]. In parallel to availability of uncertainty estimates in nuclear

data, progress in quantifying and reducing the uncertainties from the deterministic methodology was greatly advancing, with an uptake of monte carlo modelling and methods.

Reactor systems designed prior to 2000 made limited use of monte-carlo predictions, as in the 1990s only a few dozen processor could be used [12]. The uncertainty and errors of solving the Boltzmann equation, often with the 2-step method of coupling cell and diffusion codes, was at least as great as the errors in the nuclear data used in the equation. Two-step methods are still the de-facto standard in neutronics design, however, they are now commonly verified against monte carlo codes. Such code-to-code checking was initially done for static integral parameters (k-eff), but is increasingly done for local and time-dependent quantities, although it will be some time before deterministic methods are replaced [13]. As a result of verification against monte carlo methods, approximations from solving the Boltzmann equation can be well quantified, and are of decreasing importance. Thus, improving the nuclear data should directly translate into reduced biases and uncertainties of advanced modelling and simulation tools.

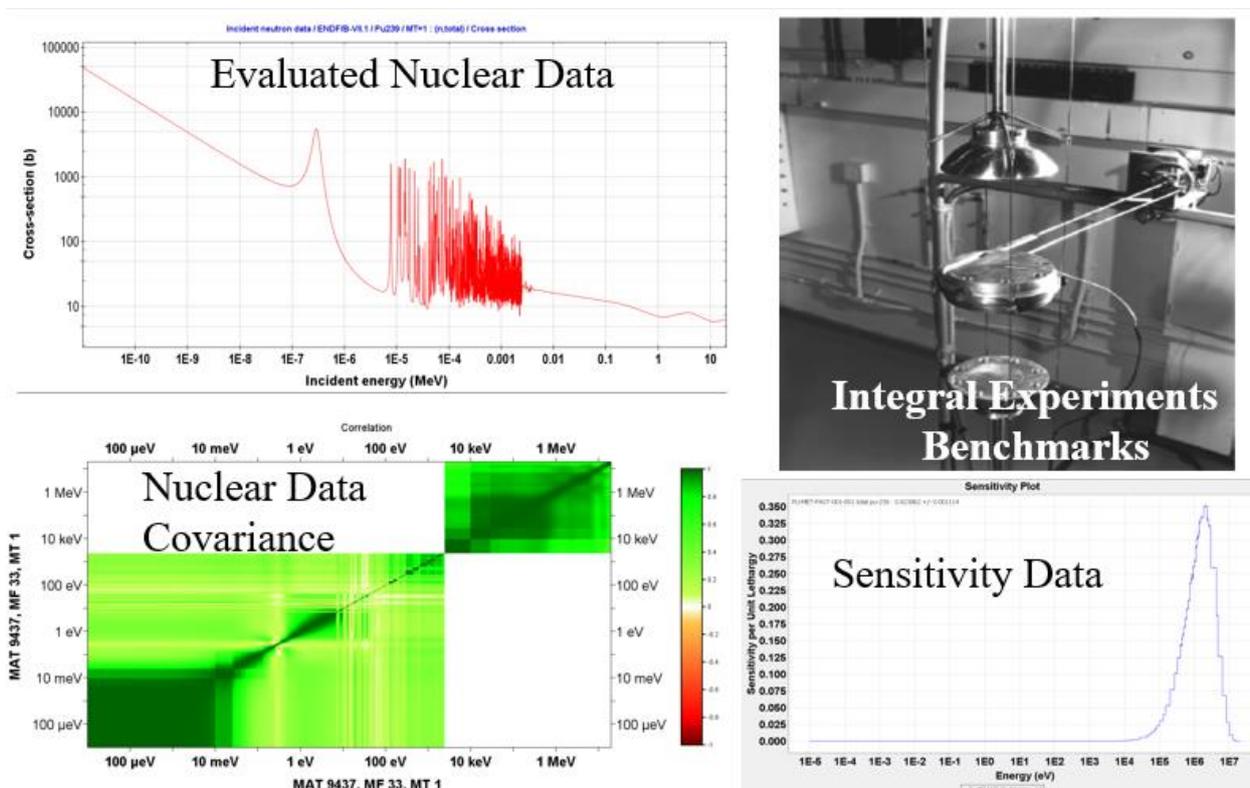

Switching tools and data is not a decision to be trivialized. For systems that already exist, measured data ensures that the biases in the modelling and simulation tools are well quantified for observable in the system, although the sources might not be always well understood. Switching data libraries results in new, unquantified biases that may be detrimental and ultimately more impactful than the reduction in uncertainty. It is rightly considered risky to change the underlying nuclear data, unless it has the accompanying verification and validation case. At the same time, inevitably, the amount of measured data is far less than the number of reactor states, and advanced simulations based on more accurate data allow better interpolation and extrapolation away from the measured state points; incentivizing the use of improved methods.

Given the above, it should be common practice for nuclear data evaluations to be vetted against the gauntlet of collected experimental data. In actuality, this is very much not the case [14,15], and it could be argued that initial integral validation efforts may even be less effective than in the past. Most of the nuclear data testing involves criticality experiments. This is done partially because:

- a) it was done before (tradition),
- b) the data are very good, well documented with models and uncertainties (ICSBEP [16]),
- c) it is relatively easy (Fast, easy to interpret, tools to pick relevant benchmarks).

Many of the predictions of other phenomena, important to reactor design go untested until the library is released. Not unique to reactor physics of operating plants, the downstream applications of nuclear data are not always considered; recently awareness has increased, and preliminary efforts to collect the downstream applications and needs have been launched [17-20].

Main elements of nuclear data validation are depicted in Fig. 1. The gold standard would be to have good reactor physics benchmarks of all relevant phenomena, coupled with tools and data that make them easy to use and test by nuclear data evaluators and validation committees. Most of the aspects are in place, with the improvement methods, codes, data, and computer power, so it is primarily a matter of coordination and mutual willingness of the communities to improve validation. Furthermore, by strengthening the link between the reactor physicists and nuclear data evaluators, new measurements needs can be clearly identified [21-22] and better direct the limited resources for new experiments. In the next section the available benchmarks in the reactor physics handbook [23] will be explored that are readily available for improved nuclear data testing.

**Figure 1. Key components of nuclear data testing and feedback.**

## 2. REACTOR PHYSICS EXPERIMENTAL BENCHMARKS FOR NUCLEAR DATA TESTING

As outlined in the previous section, nuclear data testing is skewed towards criticality benchmarks. For reactor physics benchmarks, the main source of high-quality benchmarks is compiled in the International Handbook of Evaluated Reactor Physics Benchmark Experiments [23]. The tables in the subsequent sections have been extracted from the Handbook using the IRPhEP Database and Analysis Tool (IDAT) [24], which can be used to interrogate the data contained within the Handbook.

The question can be asked, what type of experiments would be of greatest value to the nuclear data community? Recent efforts to answer this question in the context of nuclear data adjustment provide insight into a potential hierarchy of experiments for nuclear data testing. In the progressive incremental approach (PIA) [25] in order to reduce compensating errors during nuclear data adjustment, it is suggested that the following hierarchy be used for actinides [25].

1. *Fission spectral indices: sensitive to fission cross sections (but also to inelastic and fission spectrum, in the case of threshold fission cross sections)*
2. *Irradiation experiments: sensitive to capture cross sections (and second order to fission) and (n,2n)*
3. *Sample oscillation experiments and other experiment sensitive to inelastic (e. g. transmission, flat/steep adjoint, etc.)*
4. *Critical masses*
5. *Reactivity variations (both reactivity coefficients and reactivities associated to fissile isotope variations in the same core geometry)*

Similarly, this order can be applied to prioritize evaluation of experimental benchmarks and direct nuclear data testing.

Of course, many other reactor physics experiments exist, often of excellent pedigree. However, in order for the nuclear data community to embrace these experiments, additional efforts are needed to transform the experimental results into benchmarks with well defined uncertainties, as was done in the reactor physics handbook. Some high-quality experiments and experimental benchmarks will be noted in the upcoming sections.

Finally, often high-quality benchmarks are not in the public domain. The consequences are that restricted access of these benchmarks impedes the ability to improve nuclear data and tools. As institutions will eventually be pushed to adopt new tools and methods, the opportunity to efficiently integrate restricted benchmark data into the new tools will be missed. Eventually questions will be asked by experts and regulatory bodies about the impacts of using antiquated information. To remedy this, it is suggested that at a minimum, sensitivity profiles of the applications should be made publicly available and collected. Existing tools [26] can be used to provide feedback on the impact of nuclear data changes to these applications. This would improve adoption by industry, and incentivize nuclear data projects.

## **2.1. Criticality**

Understandably, nuclear codes and data can predict k-eff well for existing systems, for which there is a wealth of data. In reactor physics predicting k-eff impacts aspects such as the critical mass and fueling rate of the reactor. During the development of nuclear systems, changing the nuclear data library from ENDF/B-VI.8 to ENDF/B-VII.0 was found to lower the anticipated burnup of a next generation heavy water reactor, ACR-1000 [27], and required a significant redesign of the in core reactivity devices to maintain the advertised burnup of the fuel. While k-eff is important for reactor systems and behavior, it will not be addressed further as it is well tested by the major nuclear data libraries and new simulation tools.

## **2.2. Spectral Characteristics**

Spectral characteristics can include ratios of reaction rates from activation foils, or detailed determination of the neutron spectrum from devices such as proportional counters. Reactor systems are often compared on the basis of their neutron spectrum as this quantity acts as a surrogate for the overall system properties.

### **2.2.1 Available Measurements**

The reactor physics handbook has 233 spectral characteristics measurements performed, performed at 15 facilities as shown in Table I. The majority of measurements are reaction rates relative to either Pu<sup>239f</sup> or U<sup>235f</sup>. Facilities such as BFS1 and ZPPR have multiple experimental benchmarks where the configuration has been changed specifically to alter the neutron spectrum. As illustrated in PIA, these measurements should be used to constrain any nuclear data adjustment process. The reactor physics community needs to prioritize the preservation of these experimental data, and ensure they are made available to nuclear data testers in a convenient format.

**Table I.:** Spectral characteristic experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Ratio	Rough Uncertainty
BFS1	Fast	$Am^{241f}, Am^{243f}, Cm^{244f}, Cm^{245f}, Np^{237f}, Pu^{239f}, Pu^{240f}, Pu^{241f}, Pu^{242f}, Th^{232f}, U^{238c}, U^{238f}$	$Pu^{239f}, U^{235}$ ~3%
BFS2	Fast	$Pu^{239f}, U^{235f}, U^{238f}$	$Pu^{239f}, U^{235}$ ~3%
DCA	Thermal	$U^{238}$ **factor	~5%
DIMPLE	Thermal	$Pu^{239f}, U^{238c}, U^{238f}$	$U^{235}$ ~1%
FFTF	Fast	H <sup>1</sup> -Elastic, neutron spectrum	- ~Variable wrt Energy
IPEN	Fast	Cadmium ratio, other ratios	- ~1%
LR(0)	Thermal	H <sup>1</sup> -Elastic neutron spectrum	- ~1%
PROTEUS	Thermal	$Np^{237c}, Th^{232c}, Th^{232f}, Th^{232N,2N}, U^{233f}, U^{235f}, U^{238c}, U^{238f}$	$Pu^{239f}, Th^{232c}$ ~2%
SCCA	Fast	(Cd ratio)	~2%
SNEAK	Fast	$Pu^{239f}, U^{238c}, U^{238f}$	$U^{235f}$ ~3%
SSCR	Thermal	$Dy^{164c}$	~5%
ZEBRA	Fast	H <sup>1</sup> -Elastic neutron spectrum Li Time-of-flight $Pu^{240f}, Pu^{241f}, U^{235f}, U^{238c}, U^{238f}$	$Pu^{239f}, U^{235f}$ ~3%
ZPPR	Fast, Intermediate	H <sup>1</sup> -Elastic neutron spectrum, $U^{235c}, U^{235f}, U^{238c}, U^{238f}$	$Pu^{239f}, U^{235f}$ ~3%
ZPR	Fast, Intermediate	$U^{235f}, U^{238c}, U^{238f}$	$Pu^{239f}, U^{235f}$ ~3%
ZR6	Thermal	$Ce^{143c}, Dy^{164c}, In^{115c}, Mn^{55c}, U^{235f}, U^{238c}$	- ~2%

Many other high quality spectral characteristic measurements exist, some in critical facilities currently in the ICSBEP Handbook. While there are many BFS and ZPPR benchmarks currently in the handbook, these flexible facilities have had numerous experimental campaigns many with high-quality spectral characteristics measurements. Similar to the ZPPR in design, the FCA reactor in Japan also is a potential source of high quality data.

**High priority unevaluated measurements (known to be well documented):** ZPPR, BFS, Spectral Shift Control Reactor [28], TAPIRO [29], spectral characteristics in GODIVA, FLATOP and JEZEBEL.

### 2.3. Reactivity Effects and Coefficients

When designing nuclear systems, as was previously noted, it is crucial to accurately predict the reactivity worth of different materials and the system feedback effects. Reactivity effect measurements are likely the most common neutronics experiments performed, however they have only occasionally been evaluated into experimental benchmarks. For nuclide capture-cross-sections experiments such as those performed using pile oscillators can provide precise estimation of the reactivity worth in the given system.

Reactivity coefficients, these often are critical parameters in the safety case of reactor systems. Void reactivity, particularly in sodium fast reactors, and pressurized heavy water reactors of the utmost

importance in safety cases, and often determine the operating envelope. As performing experiments for all possible core configurations and burnups is impractical, analysts rely on computational tools to interpolate and extrapolate the experimental results at hand. Many of these experiments remain proprietary, due to their high commercial importance and safety implications.

### 2.3.1. Void Reactivity

The reactor physics handbook has 16 sodium void reactivity measurements made in 4 different facilities, as is shown in Table II.

**Table II.:** Sodium void reactivity experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Material	Method	Rough Uncertainty
BFS2	Fast	Sodium	IK	~10%
ZEBRA	Fast	Sodium	Relative to Rod Worth	~5%
ZPPR	Fast	Sodium	IK, MSM	~5%
ZPR	Fast	Sodium	Relative to Rod Worth	~10%

IK=Inverse Kinetics, MSM=Modified Source Multiplication method.

Many experimental campaigns have been performed to evaluate the sodium void effect in different systems, however the experiments remain unevaluated. As a consequence, when nuclear data cross sections are changed, they are rarely benchmarked against these configurations.

### 2.3.2. Temperature Reactivity

The reactor physics handbook has approximately 50 measurements of system responses to changes in temperature, conducted at 8 facilities as is shown in Table III. The majority of these experiments are for increases in the total system temperature. While experiments have performed high temperature measurements for both thermal and fast systems, these have not been evaluated as benchmarks.

**Table III.:** Temperature reactivity experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Temperature Effect	Temperature Range	Rough Uncertainty
CREOLE	Thermal	Core	~20C - 300C	Varies widely
FFTF	Fast	Core	~190C - 220C	~2%
HTTR	Thermal	Core	~70C - 460C	~5%
IPEN	Thermal	Core	~20C - 80C	~1%
JOYO	Fast	Core	~170C-250C	~5%
KRITZ	Thermal	Core	~40C - 250C	(To be added)%
TCA	Thermal	Core	~40C	~10%
VHTRC	Thermal	Core	~25C - 200C	~5%

### 2.3.3. Control Rod Worth

The reactor physics handbook has 50 control rod worth measurements made in 9 different facilities, as is shown in Table IV. Often both the differential control rod worth and the total worth have been benchmarked. For nuclear data testing, control rod benchmarks are of less importance, however confirmation of codes abilities to predict the transient response of systems is an important quantity that would benefit from enhanced benchmarking.

**Table IV.:** Control rod worth experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Material	Method	Rough Uncertainty
IPEN	Thermal	B10	IK	1%
PROTEUS	Thermal	Stainless Steel, Borated Steel, Copper	IK, Period Method	5%
NRAD	Thermal	B4C	Period Method, Rod Drop	10%
HTTR	Thermal	B4C	IK	5%
FFTF	Fast	B4C	MSM	5%
JOYO	Fast	B4C	Period Method	3%
ZPPR	Fast	B4C	MSM	1%
ZPR	Fast	B4C	MSM	5%
ZR6	Thermal	Gd	Relative to Water Level Change	2%

IK=Inverse Kinetics, MSM=Modified Source Multiplication method.

### 2.3.4 Available Measurements Burnup Reactivity

Only two benchmarks exist for burnup reactivity in the reactor physics handbook. The DUKE experimental benchmark was an extensive study of differences between measured and calculated neutron flux in different power reactors, and can be used to improve the integral prediction of the reactivity decrement during burnup. Many PIE measurements have been performed from fuel discharged from power reactors, and are available in the SFCOMPO database [30]; currently SFCOMPO measurements have not been transformed into benchmarks, however an international technical review group has been formed and tasked to this.

**Table V.:** Burnup reactivity experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Measurement	Typical Uncertainty
DUKE Power Reactors	Thermal	Errors in flux map, correlated to depletion reactivity	~3%
JOYO	Fast	Compared to Rod Worth	~5%

**High priority unevaluated measurements:** SPERT doppler [32], SEFOR doppler, FCA-X sodium void reactivity, Superphenix Startup measurements, EBR-II void reactivity, ZED2 void reactivity measurements, FUGEN temperature coefficient, SFCOMPO data.

## 2.4. Kinetics Parameters

Kinetics parameters play an important role in the safety analyses of nuclear reactors as they determine the transient response of the reactor. The delayed neutron fractions and time constants are often embedded in the interpretation of other experimental results, where knowledge of the kinetics parameters is used to deconvolve the measured signal into reactivity. Benchmarking of beta effective is occasionally performed, although additional efforts should be made to define the uncertainties in the data.

### 2.4.1. Available Measurements of Kinetics Parameters

**Table VI.** Kinetics parameters experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Parameter	Typical Uncertainty
BFS1	Fast	Beta	~2%
CROCUS	Thermal	Inverse Period	N/A
IPEN	Thermal	Beta	~5%
IPEN	Thermal	Generation Time	~1%
ORSPHERE	Fast	Beta	~1%
ORSPHERE	Fast	Generation Time	~10%
ORSPHERE	Fast	Prompt Neutron Decay Constant	~10%
SNEAK	Fast	Beta	~5%

**High priority unevaluated measurements (known to be well documented):** Berenice [33], FCA, experiments in [34]

## 2.6. Reaction Rate and Power Distributions

Reaction-rate measurements are flux maps, fission chamber scans, and wire-activation fine-structure and macro-structure measurements. They provide validation of the ability of the codes and nuclear data to predict the spatial distribution of neutron flux. Different materials can be employed, especially when seeking sensitivity to specific neutron spectra. Measurements can either be absolute, or relative, either to a normalizing position or average.

These measurements are of particular interest near material interfaces, such as core reflector, or near structural components. Additionally fine structure measurements of the reaction rate/power distribution within the reactor fuel is of particular interest to fuel performance codes. Table VII provides an overview of data available within the reactor physics handbook.

**Table VII.:** Reaction rate distribution experimental benchmarks in the IRPhEP Handbook

Facility	Spectrum	Technique
BFS1	Fast	Fission Chamber, Activation
BFS2	Fast	Fission Chamber
CREOLE	Thermal	Fission Chamber, Activation
DCA	Thermal	Activation
DIMPLE	Thermal	Activation
HTTR	Thermal	Fission Chamber
IPEN	Thermal	Activation
KRITZ	Thermal	Activation

LR(0)	Thermal	Activation
ORCEF	Fast	Activation
ORSPHERE	Fast	Activation
SCCA	Fast	Fission Chamber, Activation
SNEAK	Fast	Fission Chamber, Activation
TRIGA	Thermal	Fission Chamber
VENUS	Thermal	Activation
ZEBRA	Fast	Fission Chamber, Activation
ZPPR	Fast	Activation
ZPR	Fast	Activation

### 3. CONCLUSIONS

A rethink is needed about how nuclear data validation is done, and the roles and priorities of the various stakeholders. A number of candidate reactor physics experimental benchmarks have been identified as well as candidates for future evaluation. The reactor physics community needs to invest heavily in turning the highest quality experiments of the past into benchmarks. If they do not, the nuclear data community will not test against these measurements, and new libraries will not perform for applications, creating a vicious circle of disincentivization. Meanwhile, the nuclear data community needs engage with the reactor physics community, collecting their needs, and develop rapid testing methods to ensure predictions of well-known quantities do not get worse. With recent advances in perturbation theory, nuclear data covariance, the monte carlo method, and computing power all the pieces are in place for the paradigm to shift.

### ACKNOWLEDGMENTS

The International Reactor Physics Experiment Evaluation Project (IRPhEP) technical review group is acknowledged, as is the leadership of the project provided by its chair John Bess. A special thanks to the efforts of Enrico Sartori and Blair Briggs to preserve and evaluate experimental data is noted. Also, the financial contribution of the government of Japan to support the IRPhEP and the accessibility of the data is noted.
